sampled as well, if possible. Aggressive therapy with broad-spectrum, topical fortified antibiotics should be initiated immediately. A combination broad-spectrum regimen that includes either cefazolin or vancomycin and tobramycin or gentamicin is recommended. In less severe cases, aggressive broad-spectrum monotherapy with a fluoroquinolone is often effective.<sup>103</sup> Delay in treatment of more than 12 hours increase the risk of vision loss.<sup>101</sup> The Steroids for Corneal Ulcers Trial (SCUT) identified that adjunctive topical corticosteroids may be associated with improved outcomes in bacterial MK not caused by *Nocardia* spp. and that the worst ulcers benefit the most from corticosteroid application.<sup>104</sup> However, as will be mentioned later, misdiagnosis in the context of corticosteroid use can be vision threatening because corticosteroids worsen nonbacterial keratitis, such as that caused by herpes simplex virus, fungal keratitis, and *Acanthamoeba* keratitis.

Careful follow-up and adjustment of therapy, based on identification of the organism, sensitivity testing, and clinical response, are essential. Unfortunately, MK often causes corneal scarring and decreased acuity because these lesions are often centrally located; up to 25% of patients are left with best-corrected visual acuity of less than 20/200.<sup>105</sup> Patients may require corneal transplantation or RGP lens to improve acuity.

## Fungal Keratitis

Historically, fungal infections are a rare cause of contact lens–induced MK. However, the incidence of fungal keratitis is increasing, and the increase has resulted from contact lens–associated filamentary fungal infections.<sup>106</sup> All types of contact lenses, including daily disposables, have been associated with fungal keratitis.<sup>107</sup> *Candida* spp. are the most common non-filamentous isolates, and *Aspergillus* and *Fusarium* lead the filamentous causes.<sup>108</sup>

Patients present with decreased vision, injection, and pain that may be severe. Early filamentous infections have a feathery appearance at the edges and may be less dense than those seen with bacterial MK. There may be a frank epithelial defect, and the anterior chamber reaction may be mild or severe, even forming a hypopyon. MK caused by yeast infections are typically more localized, with a small epithelial defect overlying an infiltrate. Fungal MK may be slowly progressive, often delaying correct diagnosis.

Culture and Gram staining of corneal scrapings should be performed if fungal keratitis is suspected. Cultures of the solutions, lenses, and lens cases are also advised. Unlike suspected bacterial infections, which are often treated empirically pending culture results, treatment for fungal keratitis does not typically begin until confirmation with positive culture results, scrapings, confocal microscopy, or (occasionally) a corneal biopsy.

The Mycotic Ulcer Treatment Trial (MUTT) demonstrated level 1 evidence that topical natamycin is superior to topical voriconazole in the treatment of fungal keratitis, especially in cases of *Fusarium* keratitis.<sup>109</sup> Systemic voriconazole in combination with topical treatment is used in severe cases. Interestingly, some fungal keratitis associated with soft contact lens wear can resolve with topical fluoroquinolone treatment; it is postulated that fluoroquinolones augment the innate immune response.<sup>110</sup>

**Fig. 4.24.11** Patients with *Acanthamoeba* keratitis often show radial keratoneuritis (arrow) with infiltration along the corneal nerves.

## Acanthamoeba Keratitis

*Acanthamoeba* is a protozoa found in fresh water and soil and the majority of cases of *Acanthamoeba* keratitis are associated with contact lenses. The key risk factors for *Acanthamoeba* infection involve poor hygiene practices, including using tap water or saline to rinse or store lenses, swimming in fresh water while wearing contact lenses, and using hydrogen peroxide instead of multipurpose solution.<sup>111</sup> However, other studies have indicated that hydrogen peroxide is a superior lens disinfectant solution.<sup>112</sup> Overall, it has been estimated that over 80% of *Acanthamoeba* infections could be prevented with proper lens disinfectant systems.<sup>113–115</sup>

*Acanthamoeba* keratitis should be suspected in all contact lens wearers who experience foreign body sensation; severe pain out of proportion to clinical examination findings; lid edema; lack of improvement with antibiotics, antivirals, or corticosteroids; and epithelial findings, including punctate epithelial erosions, ring-shaped infiltrates, and pseudo-dendritic lesions<sup>116</sup> (Fig. 4.24.11). If a patient presents with an isolated ring-shaped corneal infiltrate and *Acanthamoeba* is not found, consideration should be given to unrelated causes, such as anesthetic abuse or a type 3 response to endotoxin (e.g., Wessely immune rings).

Definitive diagnosis entails corneal scrapings and cultures, although there is a role for preliminary confocal microscopy.<sup>117</sup> The lesion may be confused with fungal, bacterial, or herpetic keratitis, and this often leads to delay in diagnosis and treatment. Even if promptly diagnosed, vision loss may result because there is no optimal treatment for this condition that causes amebic encystation and medication resistance.

Treatment is amebicidal therapy with propamidine isethionate 0.1% and PHMB 0.02%, for months.<sup>118–121</sup> Use of topical corticosteroid can have detrimental effects on visual outcome, but its use can be considered after initiation of modern antimicrobial therapy.<sup>122</sup> Penetrating keratoplasty is often required, but infection may recur in the graft, necessitating enucleation.<sup>123–125</sup> Considering the virulence of the organism and its resistance to treatment, it is critical that proper lens hygiene is emphasized to prevent *Acanthamoeba* infection. Daily disposable lenses may be the best option for patients who exhibit less than optimal adherence to sanitation measures.

## UNSUPERVISED LENS WEAR

Unsupervised lens wear occurs when individuals inexperienced with contact lens use obtain lenses without a prescription and from unlicensed sellers. No individualized fitting occurs, and no instruction is given on any aspect of lens wear or care. These lenses are typically plano lenses worn to change the color of the eye or for some dramatic effect. The sale of these “black market” lenses occurs at unlikely locations, such as convenience stores, nail salons, beauty parlors, theatrical supply houses, flea markets, and even street vendors. These lenses also are available from Internet suppliers, some of whom advertise that no prescription is needed. The typical customer is a young person; the risks may be compounded by overnight wear of these lenses and sharing and swapping of lenses. As these lenses gained popularity, eye care professionals have started to see more cases with such problems as infectious keratitis, which sometimes result in loss of vision, hospitalization, and the need for penetrating keratoplasty.<sup>126–128</sup> In

2005, plano, or decorative, lenses were classified as medical devices requiring a prescription as a result of significant effort by professional eye care organizations and individuals and concern shared by the FDA.<sup>129</sup>

Unsupervised lens wear also occurs with prescription lenses, now readily available from alternative lens sellers. Despite the legal requirement for a valid contact lens prescription, some wearers are able to obtain contact lenses for extended periods without regular eye examinations. If a lens wearer has no acute problem requiring immediate attention, it is only at the yearly examination that eye care professionals can examine the patient for subtle signs of lens problems, review wearing and replacement schedules, and ensure that the patient is using an appropriate lens care system. In contact lens care, if there is no immediate consequence to deviation from recommended practices, a slow drift away from good lens care can occur. In 2006, the FDA issued guidelines emphasizing the importance of professional advice, valid contact lens prescriptions, and continuing professional care. FDA guidelines succinctly state: "Because of these risks, contact lenses, including decorative contact lenses that are noncorrective, are not safe for use except under the supervision of a practitioner licensed by law to direct the use of such devices."<sup>130</sup>

## FDA AND CDC RECOMMENDATIONS

The recommendations of the FDA and the Centers for Disease Control and Prevention for contact lens safety are summarized below and can be found at [www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/HomeHealthandConsumer/ConsumerProducts/ContactLenses/](http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/HomeHealthandConsumer/ConsumerProducts/ContactLenses/) and [www.cdc.gov/contactlenses/](http://www.cdc.gov/contactlenses/).

- Follow the recommended wear schedule. Do not substitute sterile saline solutions with multipurpose solutions.
- Rub and rinse your contact lenses as directed by your eye care professional.
- Do not "top off" the solutions in your case. Always discard all of the left-over contact lens solution after each use. Never reuse any lens solution.
- Clean, rinse, and air-dry your lens case each time lenses are removed.
- Do not expose your contact lenses to any water: tap, bottled, distilled, lake, or ocean water.
- Contact your eye care professional if you experience any symptoms of eye irritation or infection.

## CONCLUSIONS

The overall safety profile of contact lenses is excellent, but wearers are at increased risk for both non-sight-threatening and blinding complications.

Appropriate lens selection and patient education regarding lens hygiene can reduce complications. Public health initiatives may be required to reduce unsupervised lens wear. Regular monitoring by an eye care provider are critical to primary and secondary prevention. In the event of a contact lens-related complication, prompt referral, early diagnosis, and proper treatment typically result in good visual outcomes and allow continuation of contact lens wear.

Corneal and External Eye Manifestations of Systemic Disease

4.25

Paula Kataguirí, Kenneth R. Kenyon, Priti Batta, Hormuz P. Wadia, Joel Sugar

**Definition:** Disorders with corneal, external, and other anterior segment manifestations of systemic diseases and syndromes.

Key Feature

- External and anterior segment ocular anomalies as well as systemic abnormalities.

Associated Feature

- Usually genetic defect with multisystem clinical findings.

INTRODUCTION

As is broadly evident in multiple other ocular and orbital tissues, systemic disorders commonly exhibit ocular manifestations. Because of the multiplicity and complexity of these disorders, this chapter presents these associations largely in tabular form. Where known, the causative genetic loci and resultant metabolic defects are specified. Finally, as many disorders are genetically heterogeneous, only the more commonly associated genetic loci are listed.

CONGENITAL DISORDERS

Congenital disorders are nonmetabolic disorders present at birth that have generalized systemic features as well as ocular anterior segment abnormalities. These groupings are arbitrary and may change as genetic information allows for more specific categorizations. Some craniofacial malformation syndromes with associated anterior ocular findings are given in Table 4.25.1. Given the severity of these disorders, management is multidisciplinary and requires a team approach by ophthalmologists, facial plastic surgeons, neurosurgeons, and others.<sup>1–11</sup>

CHROMOSOMAL DISORDERS

Syndromes consequent to chromosomal disorders are defined by their abnormal genetic loci (Table 4.25.2). With rapid advances in molecular genetics, more thorough understanding of relevant regulatory or other gene mechanisms involved will allow for better interpretation of their widespread, multisystemic (also see Section I: Genetics). A striking finding is that different chromosomal defects may lead to similar phenotypic abnormalities.<sup>12–16</sup>

INHERITED CONNECTIVE TISSUE DISORDERS

The inherited connective tissue disorders are striking in their musculoskeletal manifestations and often serious in their visceral involvements

TABLE 4.25.1 Craniofacial Malformation Syndromes With Corneal Manifestations

Syndrome	Protein Defect	Gene Locus	Ocular Manifestations	Systemic Manifestations
Crouzon’s, Apert’s, and Pfeiffer’s	Fibroblast growth factor receptor-2	10q26 <sup>1</sup>	Shallow orbits, decreased motility, secondary corneal exposure	Craniofacial malformation and syndactyly (Apert’s)
Meyer–Schwickerath (oculodentodigital dysplasia)	Connexin43 (Cx43) or gap junction alpha 1 gene ( <i>GJA1</i> )	6q22–q24	Microphthalmos, microcornea, narrow palpebral fissures, blue sclera	Syndactyly, dysplastic tooth enamel and microcephaly
Goldenhar’s (oculoauriculovertebral dysplasia)			Limbal dermoids, microphthalmos, anophthalmos, lid notching, blepharophimosis	Facial asymmetry, vertebral anomalies, ear deformities, mandibular hypoplasia
Hallermann–Streiff	Connexin43	6q22–24	Microphthalmos, spontaneously resorbing cataracts, macular pigment changes, Coats’ disease	Facial malformation, hypoplastic mandible, short stature, skin atrophy

TABLE 4.25.2 Chromosomal Disorders With Corneal Manifestations

Genetic Findings	Ocular Manifestations	Systemic Manifestations
13q deletion	Hypertelorism, ptosis, epicanthal folds, microphthalmos, retinoblastoma	Growth retardation, microcephaly, facial malformation, absent thumbs
18p deletion	Ptosis, epicanthal folds, hypertelorism, corneal opacity, keratoconus, microphthalmos, strabismus	Brachycephaly, growth retardation, mental retardation
18q deletion	Hypertelorism, epicanthal folds, nystagmus, corneal opacity, microphthalmos, corneal staphyloma, microcornea	Growth retardation, mental retardation, facial malformation, microcephaly, prostate cancer, hearing loss, endocrine disorders
4p deletion (Wolf–Hirschhorn syndrome)	Hypertelorism, ptosis, microphthalmos, strabismus, cataract	Growth retardation, microcephaly, micrognathia, hypotonia seizures, epilepsy
Turner’s syndrome (45×0)	Ptosis, epicanthal folds, strabismus, rarely microcornea, blue sclera, corneal opacity	Female, short stature, webbed neck, hearing loss
Trisomy 13 (Patau’s syndrome)	Microphthalmos, corneal opacity, Peters’ anomaly, cataract, retinal dysplasia (Fig. 4.25.1)	Microcephaly, cleft lip and palate, low-set ears
Trisomy 18 (Edwards’ syndrome)	Corneal opacity, ptosis, hypertelorism, epicanthal folds, microphthalmos, colobomas, cataract, retinal dysplasia	Low birth weight; failure to thrive; brain hypoplasia; cardiac, gastrointestinal, renal, and musculoskeletal anomalies
Trisomy 21 (Down syndrome)	Shortened, slanted palpebral fissure, neonatal ectropion, later trichiasis and entropion, keratoconus, cataract	Cardiac defects, mental retardation, short stature, characteristic facies
Partial trisomy 22 (cat’s eye syndrome)	Microphthalmos, hypertelorism, colobomas	Mental retardation, microcephaly, cardiac anomalies, ear anomalies, anal atresia

**Fig. 4.25.1 Trisomy 13.** (A) Inferior nasal iris coloboma and leukocoria are present. (B) Light microscopy discloses ciliary body coloboma filled with mesenchymal tissue containing cartilage (C); note the retinal dysplasia (R). (Generally, in trisomy 13, cartilage is present in eyes less than 10 mm in size.) (C) Karyotype shows extra chromosome in group 13 (arrow). (A, Courtesy Shaffer DB. In: Yanoff M, Fine BS, editors. *Ocular pathology*, 4th ed. London, UK: Mosby; 1996. C, Courtesy Drs. B. S. Emanuel and W. J. Mellman.)

TABLE 4.25.3 Inherited Connective Tissue Disorders With Corneal Manifestations				
Disease	Biochemical Defect	Gene Locus	Ocular Manifestations	Systemic Manifestations
Marfan's syndrome	Fibrillin-I gene mutations ( <i>FBN1</i> )	15q21.1	Megalocornea, lens subluxation, high myopia, retinal detachment, microspherophakia	Long extremities, lax joints, aortic/mitral dilatation, aortic dissection
Osteogenesis imperfecta	Type I procollagen COL1A1 COL1A2	17q21.31–q22.7q22.1	Blue sclera, keratoconus, megalocornea, optic nerve compression	Bone deformities, recurrent fractures, otosclerosis, dental anomalies
Ehlers–Danlos syndrome type VIA	Lysyl hydroxylase	1p36.3–p36.2	Blue sclera, keratoconus, keratoglobus, lens subluxation, myopia, floppy eyelids, ocular fragility to trauma	Skin stretching, scarring joint hypermobility, scoliosis, tissue fragility
Ehlers–Danlos syndrome type VIB	Normal lysyl hydroxylase	Unknown	Same as VIA	Same as VIA

TABLE 4.25.4 Disorders of Protein and Amino Acid Metabolism						
Disorder	Enzyme Deficiency	Gene Locus	Metabolite Accumulated	Mode of Inheritance	Ocular Manifestations	Systemic Manifestations
Cystinosis	Probable defect of lysosomal cysteine transport protein	17p13 <i>CTNS</i> gene	Cystine	Autosomal recessive	All forms: conjunctival and corneal cystine crystals deposition, band keratopathy, blepharospasm, photophobia Infantile and adolescent forms: retinal abnormalities, occasional macular changes (Fig. 4.25.2)	Infantile form (90%): renal failure, death Adolescent form (5%): renal failure, skeletal deformities Adult form or ocular cystinosis (5%): no renal failure, nonnephropathic ocular form
Tyrosinemia <sup>a</sup> type II (tyrosinosis, Richner–Hanhart syndrome)	Tyrosine transaminase deficiency	16q22.1–22.3	Tyrosine	Autosomal recessive	Dendritiform corneal epithelial changes (branches or snowflake opacities), red eye, photophobia	Palmar–plantar hyperkeratosis, mental retardation, growth retardation, epilepsy
Alkaptonuria	Homogentisate-1, 2-dioxygenase	3q21–q23	Homogentisic acid	Autosomal recessive	Pigmentation (ochronosis) of sclera near insertion of horizontal rectus muscles, “oil-droplet” opacities in limbal corneal epithelium and Bowman’s layer, pigmented pingueculae	Joint pain and stiffness
Wilson’s disease	Defective excretion of copper from hepatic lysosomes	13q14.3–q21.1 ( <i>ATP7B</i> gene)	Copper	Autosomal recessive	Kayser–Fleischer ring, “sunflower” cataract (Fig. 4.25.3)	Liver dysfunction, spasticity, behavior disturbance, nephrotic syndrome
Lattice dystrophy type II (Meretoja’s syndrome)	Gelsolin gene defect (G654A–Finnish type) or G654T (Danish type)	9q32–34	Amyloid	Autosomal dominant	Lattice dystrophy, dry eye, light sensitivity, ptosis, glaucoma	Progressive cranial neuropathy, facial paralysis, cardiac disease

(Table 4.25.3). More detailed discussions on this topic are featured elsewhere (also see Chapters 4.3, 4.19, and 4.20).<sup>17–22</sup>

## METABOLIC DISORDERS

Numerous inherited metabolic disorders affect the eye. Frequently autosomal recessive, these disorders are often consequent to a defect or reduction of a single lysosomal enzyme (hence the broad term *lysosomal storage diseases* [LSDs]) resulting in accumulation of metabolites in multiple affected tissues. For many disorders, the specific genetic defect has been identified, and for some (notably Fabry’s disease) synthesis of the defective enzyme has facilitated enzyme replacement therapy. In contrast to most corneal dystrophies, corneas affected by metabolic disorders demonstrate abnormality in multiple cell types, affect the peripheral cornea as well as the central cornea, and may be progressive.

## Protein and Amino Acid Metabolic Disorders

As specified in Table 4.25.4, the accumulated metabolites are sometimes amenable to treatment. For cystinosis, therapy is accomplished with oral cysteamine.<sup>23–27</sup> In tyrosinemia, dietary therapy (avoiding phenylalanine and tyrosine) keeps tyrosine levels controlled.<sup>28,29</sup> Vitamin C and nitisnone may be effective for alkaptonuria.<sup>30,31</sup> Chelation therapies to reduce elevated ceruloplasmin levels in Wilson’s disease utilize D-penicillamine and trientine.<sup>32–36</sup>

## Mucopolysaccharidoses

The mucopolysaccharidoses (MPSs) comprise the quintessential LSDs because their hydrolytic enzyme defects result in progressive intralysosomal (and eventual extracellular) storage of mucopolysaccharides (more

**Fig. 4.25.2 Cystinosis.** (A) Myriad tiny opacities are highly reflective. (B) Light microscopy of unstained corneal section viewed with polarization demonstrates birefringent cystine crystals (C); E, epithelium. (A, Courtesy Shaffer DB. In: Yanoff M, Fine BS, editors. Ocular pathology, 4th ed. London, UK: Mosby; 1996.)

**Fig. 4.25.3 Wilson's Disease.** (A) Annular deposition (Kayser-Fleischer ring) of golden brown-appearing copper in the periphery of Descemet's membrane partially obstructs the view of the underlying iris. Disciform "sunflower" cataract is also present. (B) Light microscopy of unstained section shows copper deposition (arrow) in the inner portion of peripheral Descemet's membrane. (Modified from Tso MOM, Fine BS, Thorpe HE. Kayser-Fleischer ring and associated cataract in Wilson's disease. *Am J Ophthalmol* 1975;79:479-88.)

properly termed *glycosaminoglycans*) (Table 4.25.5), often with variably profound skeletal and mental consequences. Corneal clouding in varying degrees and patterns, as well as retinal pigmentary degenerations, are the hallmarks of MPS disorders caused by accumulation of heparan, keratan, and dermatan sulfates.<sup>37-52</sup>

## Sphingolipidoses

Also considered LSDs, the sphingolipidoses arise from dysfunction of catabolic enzymes, with consequent accumulation of sphingolipids (Table 4.25.6).<sup>53-59</sup> Notable among sphingolipidoses are Tay-Sachs and Niemann-Pick diseases, which are not included as they lack major anterior segment manifestations.

## Dyslipoproteinemias

The dyslipoproteinemias (Table 4.25.7) comprise a somewhat diverse group of disorders resulting from the multiplicity of lipid metabolic processes and pathways. In the anterior eye, they variably manifest as eyelid xanthelasma, corneal arcus, and corneal clouding.<sup>60-66</sup>

## Mucopolysaccharidoses

The mucopolysaccharidoses (Table 4.25.8) are LSDs whose enzyme defects occur at the intersection of both glycoprotein and glycolipid metabolic pathways.

Hence the accumulation of oligosaccharides and gangliosides result in alterations common to both mucopolysaccharidoses and sphingolipidoses.<sup>67-70</sup>

## OTHER OCULOSYSTEMIC DISORDERS

Apart from the above specified disorders, numerous other systemic diseases have ocular manifestations, and they may be grouped accordingly. Thus corneorenal syndromes are a disparate group of disorders in which corneal abnormalities combine with renal disease (Table 4.25.9).<sup>71-79</sup> Corneohepatic syndromes are less common (Table 4.25.10).<sup>80-83</sup> Oculocutaneous disorders are numerous, and here only the more prominent are specified (Table 4.25.11).<sup>84,85</sup>

## CONCLUSIONS

This largely tabular overview of systemic diseases with corneal, external, and other anterior segment involvements emphasizes broad manifestations of specific diseases and thus the critical importance of evaluating and managing the whole patient and not overfocusing on the eye alone. As understanding of the basic disease mechanisms increases, new therapeutic interventions will be instituted. One such current strategy includes enzyme replacement therapy, as for example, alpha-L-iduronidase infusions have benefited the mobility of children with MPS type I,<sup>39</sup> and alpha-galactosidase has helped alleviate clinical symptoms in patients with Fabry's disease.<sup>72</sup>

**Fig. 4.25.4 Mucopolysaccharidosis.** In Hurler–Scheie syndrome (MPS I-H/S) the cornea is diffusely clouded. (Courtesy Shaffer DB. In: Yanoff M, Fine BS, editors. Ocular pathology, 4th ed. London, UK: Mosby; 1996.)

**Fig. 4.25.5 Fabry's Disease.** Verticillate changes radiate in the superficial cornea of a female carrier.

**TABLE 4.25.5 Mucopolysaccharidoses (MPS)**

Disorder	Enzyme Deficiency	Metabolite Accumulated	Mode of Inheritance	Gene Locus	Ocular Manifestations	Systemic Manifestations
Mucopolysaccharidosis I-H (Hurler)	$\alpha$ -L-Iduronidase ( <i>IDUA</i> gene)	Heparan sulfate Dermatan sulfate Glycosaminoglycans (GAGs)	Autosomal recessive	4p16.3	Corneal clouding, pigmentary retinopathy, optic atrophy, trabecular involvement	Gargoyle facies, mental retardation, dwarfism, skeletal dysplasia, valvular heart disease, hepatosplenomegaly
Mucopolysaccharidosis I-S (Scheie's, previously MPS V)	$\alpha$ -L-Iduronidase	Heparan sulfate Dermatan sulfate	Autosomal recessive	4p16.3	Corneal clouding, pigmentary retinopathy, optic atrophy, glaucoma	Coarse facies, claw-like hands, aortic valve disease
Mucopolysaccharidosis I-H/S (Hurler–Scheie; Fig. 4.25.4)	$\alpha$ -L-Iduronidase	Heparan sulfate Dermatan sulfate	Autosomal recessive	4p16.3	Corneal clouding, pigmentary retinopathy, optic atrophy	More severe than I-S, less severe than I-H
MPS II (Hunter's)	Iduronate sulfate sulfatase (iduronate sulfatase)	Heparan sulfate Dermatan sulfate	X-linked recessive	Xq28	Rare corneal clouding, pigmentary retinopathy, optic atrophy	Similar to I-H with less bony deformity
MPS III (Sanfilippo's)	Variable, depending on type	Heparan sulfate	Autosomal recessive	17q25.3 17q21.1 12q14 Chr #14	All forms: clinically clear cornea, occasional slit-lamp corneal opacities pigmentary retinopathy, optic atrophy	All forms: mild dysmorphism, progressive dementia, hearing loss, behavior issues
MPS IV (Morquio's)	A: galactose-6-sulfatase B: $\beta$ -galactosidase	Keratan sulfate, chondroitin-6 sulfate	Autosomal recessive Autosomal recessive	16q24.3 3p21.33	Corneal clouding, optic atrophy	Severe bony deformity, aortic valve disease, normal intelligence
MPS VI (Maroteaux–Lamy)	N-acetylgalactosamine-4-sulfatase	Dermatan sulfate	Autosomal recessive	5q11–q13	Corneal clouding, optic atrophy	Similar to I-H, but normal intellect
MPS VII (Sly's)	$\beta$ -glucuronidase	Dermatan sulfate Heparan sulfate	Autosomal recessive	7q21.1	Corneal clouding	Similar to I-H

**TABLE 4.25.6 The Sphingolipidoses**

Disorder	Enzyme Deficiency	Gene Locus	Metabolite Accumulated	Mode of Inheritance	Ocular Manifestations	Systemic Manifestations
GM <sub>2</sub> gangliosidosis II (Sandhoff's disease)	Hexosaminidase B, HEX B chain	5q13	Ganglioside GM <sub>2</sub>	Autosomal recessive	Membrane-bound vacuoles within corneal keratocytes, cherry-red macula	Psychomotor retardation, hepatosplenomegaly, Mongolian spots (unusual)
Metachromatic leukodystrophy (Austin's juvenile form)	Arylsulfatase A isozymes	22q13.31-qter	Sulfatide	Autosomal recessive	Corneal clouding	Mental retardation, seizures
Fabry's disease	$\alpha$ -Galactosidase A	Xq22	Ceramide trihexoside	X-linked recessive	Conjunctival and retinal vascular tortuosity, anterior subcapsular lens opacities, oculomotor abnormalities, cornea verticillata (Fig. 4.25.5)	Renal failure, peripheral neuropathy, hypo/hyperhidrosis, hypoacusis
Gaucher's disease	Glucocerebrosidase	1q21	Glucocerebrosidase	Autosomal recessive	Prominent pinguiculae, white corneal epithelial deposits, vitreous opacities, paramacular gray ring	Hepatosplenomegaly, bone pain, anemia

TABLE 4.25.7 The Dyslipoproteinemias

Disorder	Deficiency	Gene Locus	Metabolite Accumulated	Mode of Inheritance	Ocular Manifestations	Systemic Manifestations
Lecithin–cholesterol acyltransferase (LCAT) deficiency	Lecithin–cholesterol acyltransferase	16q22.1	Free cholesterol	Autosomal recessive	Dense peripheral arcus, gray dots in central stroma, no visual changes	Atherosclerosis, xanthomas, premature coronary artery disease, hepatosplenomegaly, anemia, renal insufficiency
Fish eye disease (high-density lipoprotein lecithin–cholesterol acyltransferase)	α-Lecithin–cholesterol acyltransferase	16q22.1	Triglycerides, very low density lipoproteins (VLDL); low-density lipoproteins (LDL)	Autosomal dominant	Progressive corneal clouding, increased corneal thickness	None
Tangier’s disease (analphalipoproteinemia)	High-density lipoprotein	9q22–q31 (ABCA1 gene)	Triglycerides; low levels of high-density lipoproteins (HDL), cholesterol and phospholipids	Autosomal recessive	Fine dot corneal clouding, severe visual loss, incomplete eyelid closure, ectropion, no arcus	Lymphadenopathy hepatosplenomegaly, coronary artery disease
Hyperlipoproteinemia I (hyperchylomicronemia)	Lipoprotein lipase	8p22	Triglycerides, chylomicrons	Autosomal recessive	Lipemia retinalis, palpebral eruptive xanthomata	Xanthomas
Hyperlipoproteinemia II, hyper-β-lipoproteinemia IIA, hyper-β-lipoproteinemia IIb	LDL receptor (type IIa); defective lipid metabolism in type IIb	19p13 (type IIa); 1q21-23 (type IIb); others	Type IIa: LDL, cholesterol Type IIb: LDL, VLDL, cholesterol, triglycerides	Autosomal dominant	Both forms: corneal arcus, conjunctival xanthomata, xanthelasma	Coronary artery disease
Hyperlipoproteinemia III (dys-β-lipoproteinemia; broad β-disease)	Abnormality in apolipoprotein E	19q13.2	VLDL remnants, cholesterol, triglycerides	Autosomal recessive with pseudo-dominance	Arcus, xanthelasma, lipemia retinalis	Peripheral vascular disease, diabetes mellitus
Hyperlipoproteinemia IV (hyperpre-β-lipoproteinemia)	Lipoprotein lipase; apolipoprotein A	15q11-13; 21q11; others	Triglycerides, VLDL	Autosomal dominant	Arcus, xanthelasma, lipemia, retinalis	Vascular disease, diabetes mellitus
Hyperlipoproteinemia V (hyperprelipoproteinemia and hyperchylomicronemia)	Apolipoprotein A	11q23	VLDL, chylomicrons	Uncertain	Lipemia retinalis, no arcus	Xanthomas, hepatosplenomegaly

TABLE 4.25.8 Mucopolidoses (MI)

Disorder	Enzyme Deficiency	Gene Locus	Metabolite Accumulated	Mode of Inheritance	Ocular Manifestations	Systemic Manifestations
ML I (dysmorphic sialidosis, Spranger’s syndrome)	Glycoprotein sialidase (neuraminidase I)	6p.21.3	Sialyl-oligosaccharides	Autosomal recessive	Macular cherry-red spot, tortuous retinal and conjunctival vessels, spoke-like lens opacities, progressive corneal clouding	Coarse facies, hearing loss, normal IQ
ML II (I-cell disease)	GluNac-I-phosphotransferase	4q21–q23	Increased plasma lysosomal hydrolases	Autosomal recessive	Small orbits, hypoplastic supraorbital ridges and prominent eyes, glaucoma, megalocornea, corneal clouding	MPS I-H facies, mental retardation
ML III (pseudo-Hurler’s polydystrophy)	GluNac-I-phosphotransferase	4q21–q23	Increased plasma lysosomal hydrolases	Autosomal recessive	Corneal clouding	Milder growth and mental retardation
ML IV (Berman’s syndrome)	Possible ganglioside sialidase	19p13.3–p13.2	Sialogangliosides	Autosomal recessive	Corneal clouding retinal degeneration	Slowed psychomotor development
Galactosialidosis (Goldberg’s syndrome)	β-Galactosidase Neuraminidase	20q13.1	Sialyl-oligosaccharides	Autosomal recessive	Macular cherry-red spot, diffuse mild corneal clouding, conjunctival telangiectases	Seizures, mental retardation, hearing loss, hemangiomas

TABLE 4.25.9 Corneorenal Syndromes

Syndrome	Gene Locus	Ocular Manifestations	Systemic Manifestations
Alport’s	Xq22.3 COL4A5 2q36–q37 COL4A3-COL4A4	Posterior polymorphous corneal dystrophy, juvenile arcus, pigment dispersion, lenticonus, retinal pigmentary changes	Renal failure, hearing loss, lamellated glomerular basement membrane
Cystinosis	17p13	(See Fig. 4.25.2)	Infantile form: renal failure, death Intermediate form: renal failure Adult form: no renal failure
Fabry’s disease	Xq22	(See Fig. 4.25.5) (See Table 4.25.6)	Renal failure, peripheral neuropathy, angiokeratomas
Lowe’s syndrome (oculocerebrorenal)	Xq26.1	Corneal keloids, glaucoma, congenital cataracts	Mental retardation, amino acid urea, tubular acidosis, angiokeratomas, muscle hypotonia, subcutaneous nodules, arthropathy
Wegener’s granulomatosis	Nongenetic	Marginal keratitis, orbital disease, scleritis, episcleritis	Granulomatous vasculitis of lungs, kidneys, nasopharynx
WAGR	11p13	Superficial corneal opacity and vascularization, aniridia, glaucoma, foveal hypoplasia, optic nerve hypoplasia	Wilms’ tumor, mental retardation, craniofacial anomalies, growth retardation
Zellweger’s	2p15(PEX 13)1q2212p 13.3 (PEX 5) 7q21–q22(PEX1) 6q23–q24	Axenfeld’s anomaly, corneal clouding, glaucoma, retinal degeneration	Craniofacial anomalies, hypotonia seizures, retardation, hepatic degeneration, cystic kidneys, cardiac defects, early death

WAGR, Wilms’ tumor, aniridia, genital anomalies, and mental retardation.

TABLE 4.25.10 Corneohepatic Syndromes			
Syndrome	Gene Locus	Ocular Manifestations	Systemic Manifestations
Wilson's disease	13q14.3–21.1	Kayser–Fleisher ring (see Fig. 4.25.3)	Liver dysfunction; neurological dysfunction with dysarthria, spasticity, behavior disturbances
Zellweger's syndrome	7q21–q22	(See Table 4.25.9)	(See Table 4.25.9)
Alagille's syndrome	20p11.2–p12	Posterior embryotoxon, anterior chamber anomalies, eccentric or ectopic pupils, chorioretinal atrophy, retinal pigment clumping	Cholestatic liver disease, structural heart defects, butterfly vertebrae

TABLE 4.25.11 Oculocutaneous Disorders				
Syndrome	Protein Defect	Gene Locus	Ocular Manifestations	Cutaneous/Systemic Manifestations
Basal cell nevus syndrome	PTCH1 protein	9q22.3, 9q31, 1p32	Multiple basal cell carcinomas of the eyelid, hypertelorism	Multiple basal cell carcinomas, jaw cysts, bony anomalies
Xeroderma pigmentosum (seven types, A–G, plus variant type V)	Nucleotide excision repair (NER) enzymes (types A–G); DNA polymerase (type V)	9q22, 2q21, 3p25, 19q13, 11p12, 16p13, 13q33, 6p21	Lid neoplasms, conjunctival and corneal neoplasia, corneal exposure, drying	Basal cell carcinoma, squamous cell carcinomas, and malignant melanomas develop in sun-exposed areas
Ichthyosis (multiple types)	Filaggrin (ichthyosis vulgaris); others	1q21(vulgaris),12q11–q13, 14q11.2, X922.32, 19p 12–q12	Eyelid and lash scaling (all types), ectropion with corneal exposure (lamellar ichthyosis)	Scaly skin
Keratitis–ichthyosis–deafness syndrome	Connexin-26	13q11-12	Keratoconjunctivitis with corneal pannus formation	Ichthyosis, deafness
Ectrodactyly–ectodermal dysplasia–clefting	TP63 (p63 gene)	3q27-28	Dysplasia of meibomian glands, blepharitis, corneal pannus formation, corneal scarring	Lobster-claw deformity of hands and feet, ectodermal dysplasia, cleft lip and palate

# Acid and Alkali Burns

Naveen K. Rao, Michael H. Goldstein

# 4.26

**Definition:** Chemical exposure to the eye resulting in trauma ranging from mild irritation to severe damage of the ocular surface and anterior segment with permanent vision loss.

## Key Features

- Alkali burns typically are more severe than acid burns.
- Acute management directed at eliminating the causative agent.
- Initial evaluation includes assessment of degree of corneal epithelial injury, corneal opacity, and limbal ischemia.

## Associated Feature

- Limbal stem cell deficiency, corneal opacification, corneal perforation, glaucoma, symblepharon, cicatricial entropion, trichiasis, fibrovascular pannus.

## INTRODUCTION

Chemical exposure to the eye can result in trauma ranging from mild irritation to severe damage of the ocular surface and anterior segment with permanent vision loss. Chemical burns constitute 77%–18% of all ocular trauma.<sup>1,4</sup> The majority of victims are young men.<sup>5–7</sup> Injuries usually are caused by accidents at work or home but also may be deliberately caused by assault.<sup>5–9</sup> Many victims report not wearing proper eye protection at the time of the injury.<sup>7</sup> In the household setting, numerous chemicals exist in the form of solutions in automobile batteries, pool cleaners, detergents, ammonia, bleach, and drain cleaners. Although most injuries caused by these are mild with minimal sequelae, but in severe cases, management can be a challenge (Fig. 4.26.1).

## ALKALI INJURIES

Alkali injuries occur more frequently and are more severe than acid injuries.<sup>1,5–8</sup> Alkalis penetrate more readily into the eye compared with acids,

damaging the stroma and the endothelium, as well as intraocular structures, such as the iris, lens, and ciliary body. Common causes of alkali injury include ammonia ( $\text{NH}_3$ ), lye ( $\text{NaOH}$ ), lime ( $\text{CaOH}_2$ ), potassium hydroxide ( $\text{KOH}$ ), and magnesium hydroxide ( $\text{Mg(OH)}_2$ ).<sup>5,7,10,11</sup> Lime, found in cement and plaster, is the most common cause of alkali injury. Damage from lime injury is limited, however, because of the precipitation of calcium soaps that limit further penetration. Lye and ammonia are associated with the most severe alkali injuries. Ammonia can be detected in the anterior chamber with a rise in aqueous humor pH within seconds of exposure.<sup>12,13</sup> Irreversible intraocular damage has been noted to occur at aqueous pH levels of 11.5 or greater.<sup>14</sup>

## ACID INJURIES

Acids cause superficial damage but generally cause less severe ocular injury than alkalis, as the immediate precipitation of epithelial proteins offers some protection by acting as a barrier to intraocular penetration.<sup>15</sup> Very strong or concentrated acids, however, can penetrate the eye just as readily as alkaline solutions. Sulfuric ( $\text{H}_2\text{SO}_4$ ), sulfurous ( $\text{H}_2\text{SO}_3$ ), hydrochloric ( $\text{HCl}$ ), nitric ( $\text{HNO}_3$ ), acetic ( $\text{CH}_3\text{COOH}$ ), formic ( $\text{CH}_2\text{O}_2$ ), and hydrofluoric ( $\text{HF}$ ) acids are frequent causes of acid burns.<sup>10</sup> The most common cause is sulfuric acid, which is found in industrial cleaners and automobile batteries. Hydrofluoric acid causes the most serious acid injuries because of its low molecular weight, which allows easier stromal penetration.<sup>16</sup> The injury may be compounded by thermal burns from heat generated by the acid's reaction with water on the tear film.<sup>11</sup>

## PATHOPHYSIOLOGY

The severity of ocular injury from alkali or acid is related to the type of chemical, the concentration of the solution, the surface area of contact, the duration of exposure, and the degree of penetration. The hydroxyl ion ( $\text{OH}^-$ ) of alkaline solutions saponifies fatty acids in cell membranes leading to cell lysis, with subsequent hydrolysis and denaturation of proteoglycans and stromal collagen.<sup>17,18</sup> The hydrogen ion ( $\text{H}^+$ ) of acidic solutions alters the pH, whereas the anion causes protein binding and precipitation in the corneal epithelium and superficial stroma.<sup>19</sup> This protein precipitation produces the typical ground-glass appearance of the epithelium and acts as a barrier to further penetration. If penetration of either alkali or acid occurs, the hydration of glycosaminoglycans leads to loss of stromal clarity. Loss of proteoglycans from the stroma results in shrinkage of collagen and can lead to an acute rise in intraocular pressure (IOP) as a result of distortion of the trabecular meshwork.<sup>20</sup> The release of prostaglandins also contributes to the rise in IOP following alkali and acid injuries.<sup>19,21,22</sup> Chemical penetration into the eye may acutely damage stromal keratocytes, stromal nerve endings, corneal endothelium, iris, trabecular meshwork, and ciliary body.<sup>17,19</sup>

In addition to corneal and intraocular injury, chemical burns result in damage to the conjunctiva, limbus, and eyelids.<sup>23</sup> Damage to palpebral and bulbar conjunctiva can lead to loss of goblet cells and chronic dry eye disease.<sup>17</sup> Ischemic necrosis of the conjunctiva causes loss of vascularization at the limbus and loss of limbal stem cells, as well as infiltration of leukocytes.<sup>17,19,24</sup> Damage to the corneal epithelium with injury solely to Bowman's layer and anterior stroma may lead to recurrent corneal erosions. Damage to the limbal stem cells, however, can result in persistent corneal epithelial defects, conjunctivalization of the cornea, presence of goblet cells within the corneal epithelium, and superficial and deep neovascularization.<sup>19,23</sup> Late sequelae of severe burns include cicatrization of the conjunctiva with symblepharon formation and entropion.<sup>19</sup> Coagulation of the posterior lid margin may cause posterior displacement of meibomian gland orifices with trichiasis.<sup>17</sup>

TABLE 4.26.1 Roper-Hall Classification

Grade	Prognosis	Conjunctival Involvement	Corneal Involvement
I	Good	None	Epithelial damage
II	Good	Less than 33% limbal ischemia	Stromal haze present but iris details visible
III	Guarded	33%–50% limbal ischemia	Total epithelial loss, stromal haze obscures iris details
IV	Poor	Greater than 50% limbal ischemia	Cornea opaque, iris and pupil obscured

From Roper-Hall MJ. Thermal and chemical burns. *Trans Ophthalmol Soc UK* 1965;85:631–53.

After a chemical burn, breakdown of the blood–aqueous barrier may result in a severe fibrinous inflammatory reaction. Damage to the ciliary body epithelium can cause decreased secretion of ascorbate, resulting in impaired keratocyte collagen synthesis and deficient stromal repair because ascorbate is a cofactor in the rate-limiting step in collagen synthesis.<sup>25</sup>

Within 12–24 hours of injury, conjunctival necrosis and hydrolysis of cellular and extracellular proteins produce chemotactic inflammatory mediators that stimulate the infiltration of the peripheral cornea with neutrophils.<sup>1,17,26</sup> The neutrophils potentiate surface inflammation and release a variety of degradative enzymes such as *N*-acetylglucosaminidase and cathepsin-D.<sup>24</sup> Damage to the corneal stroma is mediated by the interaction among keratocytes, epithelial cells, and neutrophils. Stromal repair is marked by a balance between collagen synthesis and degradation.<sup>27</sup> Keratocytes are multipotent cells capable of producing new type I collagen as well as type I collagenase, a matrix metalloproteinase (MMP).<sup>28</sup> MMPs are enzymes that can degrade matrix macromolecules, such as collagen. The three major groups of MMPs include collagenases, gelatinases, and stromelysins.<sup>27</sup> Keratocyte activity may be regulated by cytokines from epithelial cells, inflammatory cells, and other keratocytes. A close interaction exists between keratocytes and the overlying epithelial cells; type I collagenase production by keratocytes is both stimulated and inhibited by epithelial cytokines.<sup>29,30</sup>

## CLINICAL COURSE

McCulley divided the course of chemical injury into four distinct phases: immediate, acute (0–7 days), early reparative (7–21 days), and late reparative (after 21 days).<sup>16</sup> Clinical findings immediately following chemical exposure can be used to assess the severity and prognosis of the injury. The Roper-Hall classification system (Table 4.26.1) provides a prognostic guideline based on corneal appearance and extent of limbal ischemia.<sup>7,31,32</sup> In grade I injury, there is corneal epithelial damage, no corneal opacity, no limbal ischemia, and a good prognosis. In grade II injury, the cornea is hazy but iris details are visible. Ischemia involves less than one third of the limbus, and the prognosis is good. In grade III injury, there is total epithelial loss, stromal haze obscuring iris details, and ischemia of one third to one half of the limbus, and the prognosis is guarded. In grade IV injury, the cornea is opaque with no view of the iris or pupil, the ischemia is greater than one half of the limbus, and the prognosis is poor.

In the acute phase during the first week, grade I injuries heal, whereas in grade II injuries, corneal clarity is recovered slowly. Grade III and IV injuries have little or no re-epithelization, with no collagenolysis or vascularization. IOP may be elevated as a result of inflammation and mechanical distortion of the trabecular meshwork or decreased because of ciliary body damage.<sup>33</sup> During the early reparative phase, re-epithelization is completed in grade II injury, with clearing of opacification. In more severe cases, delayed or arrested re-epithelization may occur. Keratocyte proliferation occurs with production of collagen and collagenase, resulting in progressive thinning and potential for perforation.<sup>33</sup>

In the late reparative phase, re-epithelization patterns divide injured eyes into two groups. In the first group, epithelization is complete or is nearly complete, with sparing of limbal stem cells. Corneal anesthesia, goblet cell and mucin abnormalities, and irregular epithelial basement membrane regeneration may persist. In the second group, limbal stem cell damage is present, resulting in corneal re-epithelization by conjunctival epithelium. This group has the worst prognosis with severe ocular surface damage characterized by vascularization and scarring, goblet cell and mucin deficiency, and recurrent or persistent erosions.<sup>33</sup> Ocular surface abnormalities may be exacerbated by symblepharon formation, cicatricial entropion, and trichiasis.<sup>19,23</sup> A fibrovascular pannus results if ulceration does not occur, compromising visual rehabilitation.

TABLE 4.26.2 Dua Classification

Grade	Prognosis	Limbal Involvement	Conjunctival Involvement	Analog Scale
I	Very good	0 clock hours (none)	0% (none)	0.0%
II	Good	Less than 3 clock hours	<30%	0.1–3/1–29.9%
III	Good	3–6 clock hours	>30%–50%	3.1–6/31–50%
IV	Good to guarded	6–9 clock hours	>50%–75%	6.1–9/51%–75%
V	Guarded to poor	9–<12 clock hours	>75%–<100%	9.1–11.9/75.1–99.9%
VI	Very poor	12 clock hours (total)	100% (total)	12/100%

From Dua HS, King AJ, Joseph A. A new classification of ocular surface burns. *Br J Ophthalmol* 2001;85:1379–83.

In 2001, Dua proposed a new classification system (Table 4.26.2) accounting for more recent advances in surgical treatment of ocular surface burns and the resultant limbal stem cell deficiency.<sup>34</sup> This system is based on clock hours of limbal involvement and percentage of total bulbar conjunctival involvement, and unlike the Roper-Hall classification system, is not based on the degree of corneal stromal haze.<sup>34,35</sup> The Dua classification system subdivides grade IV Roper-Hall injuries into three additional categories (grades IV, V, and VI) and provides more up-to-date prognostic information for the most severe ocular surface burns.<sup>34–37</sup> It also includes an analog scale, which allows for more nuanced and flexible recording of injury severity.<sup>37</sup>

## THERAPY

### Immediate Phase

Because the area and duration of contact determines the extent of subsequent injury and prognosis, immediate copious irrigation upon exposure is of paramount importance.<sup>12</sup> Irrigation should be continued for at least 15 minutes with at least 1 L of irrigant, until the pH of the ocular surface reaches neutrality. Currently available solutions include normal saline, borate-buffered saline, balanced salt solution, phosphate-buffered saline, lactated Ringer’s, and amphoteric solutions that aim to chelate acids and alkalis and create a reverse osmotic gradient to draw chemicals out of the cornea.<sup>12,38,39</sup> Some authors discourage the use of phosphate-buffered saline, which may lead to precipitation of calcium in the corneal stroma.<sup>39</sup> Borate-buffered saline and amphoteric solutions were found to be most effective in reducing aqueous humor pH after an alkali burn.<sup>38,39</sup> Normal saline and tap water were found to be intermediately effective, and phosphate buffered saline and lactated Ringer’s were found to have the least effective buffering capacity.<sup>39,40</sup> If access to commercial irrigating solutions is not immediately available, tap water should be used despite the fact that it is hypo-osmolar and may contribute to corneal edema.<sup>12</sup> If an acid burn is suspected, a base should never be used for irrigation in an effort to neutralize the acid. A retained reservoir of chemical in the fornices should be suspected if neutrality cannot be achieved, especially with exposure to lime, which can be embedded in the fornices and the upper tarsal conjunctiva.<sup>33</sup> Eversion of the lids and removal of particulate matter should be performed; a cotton-tipped applicator soaked in ethylenediaminetetraacetic acid 1% may help with the removal of stubborn lime particles.<sup>41</sup> Necrotic corneal and conjunctival tissues should be debrided to promote re-epithelization because this debris provides a stimulus for continued inflammation with recruitment of neutrophils and mucous membrane pemphigoid production.<sup>41</sup>

### Acute and Reparative Phases

After irrigation, all efforts should be made to promote epithelial wound healing, prevent infection, reduce inflammation, minimize ulceration, and control intraocular pressure. Topical antibiotics should be used if there is any corneal or conjunctival epithelial defect. Topical and systemic ocular hypotensive medications may be needed. Better outcomes can be expected with prompt re-epithelization, while delayed or absent re-epithelization may require surgical intervention. Bandage contact lenses or amniotic membrane transplantation may be used to promote epithelial healing.<sup>35,36</sup> Intensive topical corticosteroid therapy every 1–2 hours in the first 1–2 weeks decreases the inflammatory response that can delay epithelial migration, and thus helps enhance re-epithelization in the early phases of injury.<sup>7,42</sup> Corticosteroid use in the first 10 days of injury has no adverse effect on outcome with little risk of sterile ulceration.<sup>43</sup> Prolonged use of

corticosteroids, however, can be deleterious since corticosteroids can blunt stromal wound repair by decreasing keratocyte migration and collagen synthesis.<sup>44</sup> Beyond 2 weeks at the peak of the early reparative phase, suppression of keratocyte collagen production by continued use of corticosteroids may offset the benefits of inflammatory suppression and lead to stromal ulceration.<sup>44,45</sup> Corticosteroid use should, therefore, be stressed in the first 2 weeks with subsequent taper as dictated by clinical examination. Medroxyprogesterone 1% is a synthetic progestogenic corticosteroid that has weaker anti-inflammatory activity compared with corticosteroids. Medroxyprogesterone inhibits collagenase, but unlike corticosteroids, it minimally suppresses stromal wound repair.<sup>44</sup> As such, medroxyprogesterone can be substituted for corticosteroid after 10–14 days if worsening ulceration is of concern.

Topical ascorbate 10% drops every 2 hours, topical citrate 10% drops every 2 hours, and systemic ascorbate (2000 mg per day in divided doses) restore levels depleted from the aqueous following alkali injury.<sup>7</sup> Ascorbate is a cofactor in the rate-limiting step of collagen synthesis and has been shown to decrease the incidence of stromal ulceration.<sup>46</sup> Citrate is a calcium chelator that decreases intracellular calcium levels of neutrophils and thus impairs chemotaxis, phagocytosis, and release of lysosomal enzymes.<sup>47</sup> Applied topically, citrate has been shown to reduce corneal ulceration and perforation.<sup>48</sup> Tetracyclines have been shown to offer protection against collagenolytic degradation. Proposed mechanisms for inhibition of mucous membrane pemphigoid include suppression of neutrophil collagenase and epithelial gelatinase gene expression, inhibition of  $\alpha_1$ -antitrypsin degradation, and scavenging of reactive oxygen species.<sup>27</sup> Autologous serum tears may also be a useful adjunct medical therapy. Topical amniotic membrane suspension drops have been shown to speed epithelial healing in animal models.<sup>49</sup> Topical and subconjunctival bevacizumab as well as subconjunctival triamcinolone have been reported to decrease corneal neovascularization after alkali burns in animals.<sup>50,51</sup>

## Surgical Therapy

Surgical interventions that may help stabilize the ocular surface after severe chemical injury include tarsorrhaphy to promote epithelial healing, superficial keratectomy to remove localized corneal pannus from focal limbal stem cell deficiency, limbal stem cell transplantation for diffuse limbal stem cell deficiency, and amniotic membrane transplantation. Tenoplasty and amniotic membrane transplantation are additional strategies to aid epithelial healing. Tenoplasty attempts to re-establish vascularity to ischemic areas of the limbus and to promote re-epithelization.<sup>52</sup> In this procedure, all necrotic conjunctival and episcleral tissues are excised, Tenon's capsule is bluntly dissected, and the resultant flap with its preserved blood supply is advanced to the limbus. Limbal stem cell transplantation is covered in Chapter 4.30.

The amniotic membrane is the innermost layer of the placenta and consists of a stromal matrix, a thick basement membrane, and a single epithelial layer. Amniotic membrane transplantation (AMT) has been found to reduce proteolytic activity, increase goblet cell density, and down-regulate conjunctival and corneal fibroblasts.<sup>53–56</sup> These actions are beneficial in restoring the ocular surface, especially in Roper-Hall grades II and III chemical burns, and may be considered in the acute or reparative phases.<sup>56,57</sup> Success of AMT in the treatment of grade IV injury may be limited because of stem cell loss and ischemia; when used in conjunction with limbal stem cell transplantation, however, AMT may provide a substrate for stem cell proliferation and re-epithelization.<sup>53,57–60</sup> The amniotic membrane has been shown in some studies to promote more rapid corneal re-epithelization and to reduce ocular surface inflammation, vascularization, and scarring. Other studies, however, show similar epithelial healing times and similar long-term outcomes whether or not AMT was performed.<sup>36,61</sup> If surgical amniotic membrane placement in the operating

room is either not possible or impractical, a sutureless cryopreserved amniotic membrane patch is commercially available preloaded in a symblepharon ring and can be easily inserted in the office or at the bedside.<sup>62</sup> Freeze-dried amniotic membrane preparations also are available and can be placed on the cornea under a bandage contact lens.

Penetrating keratoplasty (PKP) and deep anterior lamellar keratoplasty (DALK) for visual rehabilitation after chemical injury can be fraught with complications. Prognosis is poor in the setting of glaucoma, hypotony, limbal stem cell dysfunction, conjunctival cicatrization, entropion, and trichiasis.<sup>19</sup> If intraocular complications are minimized in the setting of an optimized ocular surface and limited deep stromal vessels, PKP or DALK may be performed with favorable results. A large-diameter PKP with or without donor limbal tissue may be considered in the acute and chronic setting.<sup>63–65</sup> Corneal transplantation provides tectonic support in the event of an impending perforation, and the limbal stem cells of the donor address ocular surface issues.<sup>63,64</sup> Staged surgery with limbal stem cell transplantation followed by PKP at least 6 weeks later has been shown to significantly decrease the likelihood of corneal graft failure.<sup>66</sup> When it is not possible to rehabilitate the ocular surface adequately, keratoprosthesis surgery may be considered.

# Corneal Surgery

Allister Gibbons, Ibrahim O. Sayed-Ahmed, Carolina L. Mercado, Victoria S. Chang, Carol L. Karp

# 4.27

**Definition:** Corneal procedures performed to either restore vision or restore globe integrity.

## Key Features

- Careful preoperative preparation and planning are critical to success.
- Understand intraoperative and postoperative complications and management.

## Associated Feature

- Be alert to the signs and symptoms of graft rejection.

## KERATOPLASTY

### Introduction

The successful outcomes enjoyed by patients who undergo modern penetrating keratoplasty (PKP) and lamellar keratoplasty are the result of advances in technology and surgical techniques.

### Historical Review

Corneal grafting techniques were pioneered by ophthalmologists, such as Reisinger,<sup>1</sup> von Hippel,<sup>2</sup> and Elschmig.<sup>3</sup> Today keratoplasty is the most common and successful human transplantation procedure, with over 45 000 corneal transplantations performed in the United States each year.<sup>4</sup> The number of PKP decreased to less than 20 000 in the year 2014, and the number of endothelial keratoplasty (EKP) increased to over 25 000 in that same year.<sup>4</sup> Optical results have improved significantly as a consequence of advances in tissue selection and preservation, techniques, trephines, and management of postoperative astigmatism.

Lamellar grafts date back to 1886 when von Hippel<sup>2</sup> successfully performed the first lamellar grafting in a human. Lamellar techniques have revolutionized the treatment of corneal diseases by offering such advantages as faster visual recovery, less postoperative astigmatism, and decreased risk of suture-related complications compared with PKP. Because “selective keratoplasty” replaces only the diseased tissue, the risk of graft rejection is theoretically lower. EKP now has become the standard of care for endothelial diseases.

### Anesthesia

Corneal transplantation may be performed under cover of regional or general anesthesia, depending on patient preference and cooperation. Typically, local anesthesia entails peribulbar or retrobulbar injection of lidocaine 2%, bupivacaine 0.75%, and hyaluronidase. A lid block may be employed to prevent squeezing.

### Specific Techniques

#### Penetrating Keratoplasty

PKP involves full-thickness replacement of corneal tissue with a healthy donor graft.

#### Preoperative Evaluation and Diagnostic Approach

PKP may be used to provide tectonic support (as in corneal thinning or perforation) and to improve visual outcomes (as in the replacement of

an opaque or irregular cornea). Indications for PKP include keratoconus; previous graft failure or rejection; full-thickness or deep corneal scars; Fuchs’ endothelial dystrophy; pseudo-phakic or aphakic bullous keratopathy; chemical burn; corneal ulcer; corneal dystrophy and degeneration; herpetic keratitis; trauma; or any other causes of corneal decompensation. Conditions with primarily posterior pathologies, such as Fuchs’ endothelial dystrophy and pseudo-phakic or aphakic bullous keratopathy, now are commonly treated with EKP. The rate of success of PKP is excellent, but the long-term risk of graft rejection increases significantly with active or recurrent infection, inflammation, corneal neovascularization, previous graft rejection, and each subsequent penetrating graft.

It is important to perform a careful preoperative evaluation and have a thorough discussion with patients about the surgery, visual expectation, possible complications, and the long postoperative course. The recipient must be prepared for the lifelong care required. In general, important considerations for the preoperative evaluation for PKP are as follows:

- Visual potential must be evaluated.
- Ocular surface must be optimized before a planned PKP. Conditions that may affect the ocular surface include rosacea, dry eyes, blepharitis, trichiasis, exposure keratopathy, ectropion, and entropion.
- Intraocular pressure (IOP) must be controlled adequately prior to surgery.
- Ocular inflammation must be recognized and treated.
- Previous corneal diseases and vascularization must be considered. A history of herpetic keratitis significantly reduces the chance of graft success because of several factors, including recurrent disease in the graft, neovascularization, trabeculitis with increased IOP, and persistent inflammation that may induce rejection.

#### Donor Selection

The Eye Bank Association of America has developed a set of criteria for donor corneas.<sup>5,6</sup> Contraindications for the use of donor tissue for PKP include the following:

- Death as a result of an unknown cause.
- Central nervous system diseases, such as Creutzfeldt–Jakob disease, subacute sclerosing panencephalitis, rubella, Reye’s syndrome, rabies, meningitis, and infectious encephalitis.
- Systemic infections, such as human immunodeficiency virus (HIV) infection, hepatitis viruses B and C infection, septicemia, syphilis, Ebola, and infective endocarditis, as well as other relevant communicable diseases, such as West Nile virus, vaccinia virus, or Zika virus infections.
- Leukemia or actively disseminated lymphomas.
- History of melanoma with known metastatic disease.
- Eye diseases, such as retinoblastoma, malignant tumors of the anterior segment, and active ocular inflammation (e.g., uveitis, scleritis, retinitis, and choroiditis).
- Prior ocular surgery, including refractive procedures. (Eyes with previous laser photorefractive surgery may be used for tectonic grafts and posterior lamellar procedures, and pseudo-phakic eyes and eyes that have undergone glaucoma filtration surgery may be used if they meet endothelial criteria by specular microscopy.)
- Congenital or acquired anterior segment abnormalities, such as corneal scars, keratoconus or Fuchs’ endothelial dystrophy, or associated conditions, such as Down syndrome (for penetrating or anterior lamellar keratoplasty).

Prior to PKP, the donor’s history and blood must be evaluated for communicable diseases, and donor tissues are inspected by the surgeon with the slit lamp.

### Surgical Techniques

Adequate decompression of the globe is ensured prior to PKP because excessive preoperative IOP may increase the risk of expulsive choroidal hemorrhage. Intravenous mannitol or mechanical ocular decompression can be considered to reduce IOP. Miotics are placed preoperatively to protect the lens during surgery unless lenticular surgery also is planned. Scleral supporting (Flieringa) rings may be used principally in aphakic eyes or young patients.

The size of the graft is determined on the basis of the location of the pathology and on clinical judgment. The donor tissue usually is 0.25 mm larger in diameter compared with the recipient tissue. In certain circumstances, a larger (0.5 mm) donor may be considered in an aphakic eye to induce myopia, or a same-size donor button, such as in a recipient with keratoconus, may be chosen to reduce myopia. The visual axis of the recipient cornea is marked with a marking pen. An inked radial keratotomy marker may be used to mark the peripheral cornea. A donor corneal button is punched. In the United States, the most commonly used trephine is the Barron Donor Cornea Punch (Fig. 4.27.1). The donor is cut from endothelium to the epithelium. The donor also may be cut from the epithelium to the endothelium by using an artificial anterior chamber and then by using the same technique described for the recipient cornea. This has the theoretical advantage of both the donor and the recipient being cut in the same fashion with the same type of blade, which reduces donor–recipient disparity and potentially reduces astigmatism.

The recipient cornea may be cut using a variety of trephines, such as the Hessburg–Barron suction trephine (Fig. 4.27.2), Hanna trephine, or Castroviejo trephine. More recently, the use of the femtosecond laser to cut the recipient cornea has been described.<sup>7</sup> Excision of the host corneal button may be performed via partial-thickness trephination followed by a controlled entry into the anterior chamber using a No. 75 blade, or via a continued trephination that is stopped as soon as aqueous egress shows the anterior chamber has been entered. If viscoelastic was not placed into

the anterior chamber prior to host trephination, it may be placed to protect intraocular structures. The recipient button is then excised using forceps and corneal scissors (Fig. 4.27.3). The edge of the recipient bed is made perpendicular for optimal graft–host apposition.

If the patient requires concurrent cataract extraction, intraocular lens (IOL) explantation, iridectomy, anterior vitrectomy, or a secondary IOL, this may be done prior to trephination if visualization allows. Because the diseased cornea precludes adequate visualization in many cases, an “open sky” technique is utilized after trephination (Fig. 4.27.4). In cases of emergent grafting, such as in the setting of an active infectious process, uncontrolled inflammatory disease, or a recent perforation, an iridectomy is performed to avoid pupillary block.

**Fig. 4.27.1 The Corneal Donor Button Is Cut.** A Barron donor cornea punch may be used to cut the donor tissue from the endothelial side.

**Fig. 4.27.2 Hessburg–Barron Vacuum Trephine.** A vacuum corneal trephine may be used to trephinate into the host cornea.

**Fig. 4.27.3 Excision of the Corneal Button.** The corneal button is removed completely using corneal scissors.

**Fig. 4.27.4 Replacement of Anterior Chamber Intraocular Lens.** (A) Care is taken when the anterior chamber haptics are removed, as they may become encysted in the peripheral iris and bleeding may occur on removal. (B) An anterior vitrectomy is performed—an iris hook may be used to improve visualization. (C) A 10-0 Prolene suture is passed beneath the iris, through the scleral sulcus and out through the previously prepared scleral flap. After the suture-supported lens is placed in the sulcus, the suture is tied to itself beneath the scleral flap. Alternatively, the knot may be rotated beneath the sclera. This is performed on both sides. (Courtesy Dr. W. W. Culbertson.)

**Fig. 4.27.5 The Corneal Button Is Placed.** Care is taken in the placement of cardinal sutures to ensure appropriate distribution.

**Fig. 4.27.6** Placement of 10-0 nylon interrupted sutures in a corneal transplant.

Viscoelastic may be placed in the anterior chamber, and the donor button then is placed over the recipient bed and sutured in place with four cardinal sutures (Fig. 4.27.5). Care is taken in the placement of the cardinal sutures, as proper tissue distribution is paramount. The depth of suture is 90% of the corneal thickness. The remaining sutures may be a combination of interrupted and running sutures or solely interrupted sutures (Fig. 4.27.6). Interrupted sutures are suited for vascularized or thinned cornea, as subsequent selective removal may be necessary to prevent the advancement of vessels or to control astigmatism. Running sutures have the advantage of speedy placement intraoperatively and better tension distribution but are more difficult to adjust. Prior to the placement of the final sutures, the viscoelastic material in the anterior chamber is removed. The running sutures may be adjusted intraoperatively by using a keratoscope. When the suturing is complete, all sutures are rotated such that the knots are buried within the stroma, and the security of the wound is tested for water tightness by using a combination of a surgical sponge and fluorescein.

### Complications and Postoperative Management

Intraoperative complications include poor graft centration, bleeding, damage to ocular structures (e.g., donor endothelium, iris, lens, or lens capsule), or expulsive suprachoroidal hemorrhage. During excision of the recipient button, it is imperative to continuously monitor the depth of the anterior chamber and the red reflex. A sudden shallowing of the anterior chamber or disappearance of the red reflex may signify an impending expulsive choroidal hemorrhage. Sealing of the globe can be accomplished quickly by a gloved finger over a partially excised host cornea or with placement of a donor cornea or temporary keratoprosthesis. The key management strategy is to close and repressurize the globe.

The success of PKP depends significantly on adequate postoperative care and management. The surgeon must be able to recognize and manage a variety of possible complications, such as wound leak, infection, glaucoma, and graft rejection or failure. The common postoperative complications and their management are discussed in the following subsections.

**Wound Leak.** A shallow anterior chamber in a soft globe the day after PKP may indicate a wound leak, which may need patching, aqueous

**Fig. 4.27.7** Subepithelial infiltrates secondary to subepithelial graft rejection. (Courtesy Dr. W. W. Culbertson.)

suppressant, lubrication, or bandage contact lenses. Resuturing of the wound may be required if the leak is significant.

**Flat Anterior Chamber With Increased Intraocular Pressure.** Flat anterior chamber with increased IOP may result from pupillary block, anterior rotation of the lens–iris diaphragm (as found in choroidal hemorrhage), choroidal effusion, or aqueous misdirection. The cause must be identified and treated.

**Endophthalmitis.** Postoperative endophthalmitis, a devastating complication, may result from a variety of factors, including contamination of donor tissue, prior infection in the host, or postoperative infection acquired through a wound leak.

**Persistent Epithelial Defect.** Epithelial defects that persist beyond 1–2 weeks occur more commonly in eyes that have ocular surface disorders, such as limbal stem cell deficiency, neurotrophic keratopathy, dry eye disease (DED), blepharitis, exposure keratopathy, and rosacea. Treatment includes frequent lubrication with preservative-free drops and lubricating ointment. Possible causes of ocular surface toxicity, such as topical eyedrops, must be eliminated or minimized. If the defect does not heal, ophthalmic blood derivatives, a tarsorrhaphy, or punctal occlusion may be necessary.

**Primary Graft Failure.** Primary graft failure (which is different from graft rejection) is recognized when significant edema of the donor tissue in a noninflamed eye is present on the first postoperative day and does not clear by 2–4 weeks. Primary graft failure may be attributed to either poor donor endothelial function or iatrogenic damage to the donor tissue during PKP. The graft is observed for several weeks. Graft failure should be differentiated from Descemet's membrane detachment. A regrant (either repeat PKP or EKP) is considered if the corneal edema fails to resolve.

**Suture-Related Problems.** Loose or broken sutures must be removed to prevent associated infection or neovascularization, which can increase the likelihood of rejection.

**Graft Rejection.** Graft rejection remains the most common cause of graft failure. The overall incidence of endothelial graft rejection has been reported as 20%.<sup>8</sup> Symptoms include decreased vision, redness, photophobia, and pain; however, patients may experience as few as one or even none of these symptoms. Patients must be educated carefully about these symptoms and must be instructed to seek medical attention immediately should they occur.

Graft rejection may be divided anatomically into three categories:

- **Epithelial rejection**—may be recognized by observation of an epithelial line. This is seen early before the host epithelium replaces the donor epithelium.
- **Subepithelial rejection**—multiple subepithelial infiltrates limited to the corneal graft may be observed (Fig. 4.27.7).
- **Endothelial rejection** (the most severe type of rejection)—characterized by keratic precipitates, iritis, and corneal edema. A Khodadoust line

**Fig. 4.27.8 Graft Rejection.** Note the inflammatory precipitates and Khodadoust line secondary to endothelial rejection. (Courtesy Dr. A. Galor.)

may be seen, which represents the advancing front of the host's inflammatory cells against a receding front of donor endothelium (Fig. 4.27.8).

The treatment of graft rejection consists primarily of corticosteroids, usually in topical form. The frequency of the corticosteroid drops is increased to hourly or even more often in the case of endothelial graft rejection until the process is reversed. Subconjunctival or Subtenon's injection of corticosteroids may be used. Systemic corticosteroids (oral or intravenous) also may be utilized in severe cases. For patients with a history of multiple rejection episodes either in the current cornea or previous grafts, systemic immunomodulatory therapy may be considered.

**Treatment for Astigmatism.** Adequate control of postoperative astigmatism is vital to achieving the best-corrected visual acuity possible. Typically starting at 8–12 weeks after PKP, the patient is followed using serial corneal topography. Subsequently, interrupted sutures are removed selectively, and running sutures are adjusted, as necessary to reduce astigmatism.<sup>9</sup> Early suture removal may have a more significant effect on astigmatism, although care is required with regard to wound stability.

**Corneal Ulcers.** Patients who have undergone PKP are more susceptible to infectious keratitis. Such factors as loose sutures and persistent epithelial defects may contribute to the development of corneal ulcers.

**Recurrence of Diseases.** Various corneal dystrophies and infections may recur in grafts. Among the three most common stromal corneal dystrophies [macular, granular (Fig. 4.27.9), and lattice], lattice corneal dystrophy has the highest recurrence. In the setting of keratic precipitates on a graft in a patient who has a history of herpes simplex virus infection, it is sometimes difficult to distinguish recurrence of a disease from graft rejection. It is important, however, to make such a distinction as the treatment for a recurrence of herpes simplex virus (antiviral agent  $\pm$  corticosteroid) is different from treatment for rejection (corticosteroid alone). The observation of keratic precipitates and corneal edema confined only to the donor button may suggest graft rejection. Anterior chamber paracentesis and polymerase chain reaction analysis can aid in the diagnosis.

### Anterior Lamellar Keratoplasty

A concept that has gained popularity in the treatment of corneal disease is the selective removal of only the diseased tissue. Lamellar keratoplasty is a procedure in which a partial-thickness graft of donor tissue is used to provide tectonic stability or optical improvement.<sup>10</sup> A partial-thickness section of donor stroma or sclera may be used. Two types of lamellar keratoplasty exist: anterior lamellar keratoplasty (ALK) and posterior lamellar keratoplasty (also referred to as *endothelial keratoplasty*) (see Chapter 4.29).

In ALK, the transplanted tissue does not include corneal endothelium, thus avoiding endothelial rejection and allowing donor tissue to be obtained from older eyes. Indications for ALK mainly include anterior corneal pathology in which the posterior cornea is unaffected, such as keratoconus, anterior corneal scars, and corneal dystrophies limited to the stroma. Femtosecond lasers can aid in this procedure.<sup>11,12</sup> A subtype of ALK is deep anterior lamellar keratoplasty (DALK), in which the objective is to eliminate all of the host stromal tissue; this can be achieved through the use of manual dissection,<sup>13</sup> viscoelastic, or an air bubble,<sup>14</sup> to dissect the host's stromal–Descemet's membrane interface.

**Fig. 4.27.9 Recurrence of Granular Dystrophy in a Graft.** (A) Slit-lamp photograph of a granular dystrophy recurrence in a penetrating keratoplasty graft. (B) Anterior segment optical coherence tomography (AS-OCT) image of recurrence showing location on Bowman's layer. (Courtesy Dr. C. Karp.)

### Preoperative Evaluation and Diagnostic Approach

A tectonic graft is performed to reinforce areas of perforated or thinned cornea. Optical lamellar grafts are used to replace diseased anterior cornea to improve visual function and require that the posterior stroma of the recipient is healthy.

The rationale for a lamellar keratoplasty and the various surgical options must be thoroughly discussed with patients. Different modalities can be used to assess the depth of a scar, the adequacy of the planned remnant stromal bed, and the severity of endothelial disease, including topography, anterior segment optical coherence tomography (AS-OCT), and specular microscopy.

### Donor Selection

**Donor Preparation.** Criteria for donor tissue selection and screening are the same as those listed for PKP except that tissue with local eye disease affecting the corneal endothelium or previous ocular surgery that does not compromise the corneal stroma (e.g., a history of endothelial dystrophy or iritis) are acceptable.<sup>5</sup>

In ALK, a fresh or frozen whole donor eye or a corneoscleral donor and artificial anterior chamber may be used to fashion the anterior lamellar donor tissue. When done manually, an incision is made just inside the limbus of the donor cornea to reach the depth of the desired dissection. A Martinez dissector or a cyclodialysis spatula is used to extend the dissection plane within the corneal stroma and harvest the donor tissue (Fig. 4.27.10). The tissue harvested may be circular, annular, or any other shape, depending on the needs of the patient (Fig. 4.27.11). Both the cornea and the sclera may be used. Usually, the donor tissue is slightly oversized (0.25–0.5 mm) in width and thickness compared with the recipient bed.<sup>15,16</sup> Donor tissue suitable for PKP should be available in case of a large perforation that may occur in the lamellar dissection of the host tissue. Newer microkeratomes allow for more efficient host and donor dissection. In particular, the femtosecond laser has been helpful in performing lamellar keratoplasty.<sup>11</sup>

### Surgical Techniques

**Anterior Lamellar Dissection of the Host Tissue.** A measurement of the affected area is done, and this can be facilitated by OCT preoperatively. A trephine is used gently to mark the extent of graft needed. The surgeon may opt for a manual dissection of the host stroma or air-assisted dissection using the “big bubble” technique, as described by Anwar.<sup>17</sup> Irrespective of the technique chosen, the goal is to create a smooth, uniplanar recipient bed. Elimination of most or all of the host stroma will lead to better final

## SEPARATION OF CADAVERIC CORNEA

**Fig. 4.27.10 Separation of the Cadaveric Cornea.** A dissector, such as the Martinez dissector or a cyclodialysis spatula, is used to gently separate the cornea along the lamellar cleavage plane through the entire cornea.

## PARTIAL-THICKNESS TREPHINATION

**Fig. 4.27.12 Partial-Thickness Trephination.** This is performed on the host in the desired location and to the desired depth. Care must be taken not to perforate the cornea.

## HORSESHOE OR ANNULAR LAMELLAR GRAFT

**Fig. 4.27.11 Donor Tissue Is Harvested.** A trephine is placed on the cadaveric globe in the size and shape desired. A horseshoe or annular lamellar graft is being harvested here. A combination of corneal and scleral tissue may be harvested to give a different tissue shape.

## DISSECTION OF DISEASED AREA

**Fig. 4.27.13 Dissection of the Diseased Area.** The diseased area in the host cornea is dissected gently to create a uniplanar, disease-free bed.

visual outcomes by eliminating stroma-to-stroma interface. If Descemet's membrane is violated, the procedure is then converted to a PKP, although conversion may be avoided in the setting of small perforations.

If a manual dissection is chosen, a partial-thickness trephination is performed until the desired depth of dissection is reached (Fig. 4.27.12). Alternatively, a microkeratome or femtosecond laser may be used for the host.<sup>11</sup> A blade is then used to extend the dissection plane along the entire host corneal tissue until the dissection of the host tissue is completed (Fig. 4.27.13). In manual ALK, the edge of the host bed should be undermined to create a horizontal groove using a Paufigue knife.<sup>16</sup> The donor lamella is placed on the recipient bed and secured with interrupted 10-0 nylon sutures (Fig. 4.27.14). The depth of the suture is about 90% of the corneal

stromal depth. The donor tissue margins should not ride anteriorly to the rim of the recipient bed. At times, an anterior chamber paracentesis may become necessary before lamellar sutures are placed. ALK may be performed centrally or in the periphery for corneoscleral melts (Figs. 4.27.15 and 4.27.16).

In DALK, a deep anterior lamellar disc is trephined to about 80% total depth, or the femtosecond laser can be used for this part of the procedure.<sup>12</sup> A paracentesis can be done at this point to inject a small air bubble in the eye to improve visualization of the big bubble because it will push it to the periphery of the anterior chamber; a mild decrease in anterior chamber pressure will also decrease resistance to the big bubble. Some surgeons advocate debulking of the anterior half of the stroma before proceeding with air dissection, whereas others proceed directly with a 27-gauge needle or cannula (previously having created a track with a dissector) to the center

of the cornea (Fig. 4.27.17). Using a 5-cc syringe, air is applied firmly to create a bubble. Two types of bubbles have been described. A type 1 bubble occurs when the stroma is dissected at the level of pre-Descemet's layer; this yields a smaller bubble with greater structural integrity (higher bursting pressure). A type 2 bubble occurs when the cleavage happens between Descemet's and pre-Descemet's layers, producing a larger bubble with a thinner wall and a lower bursting pressure.

Viscoelastic material may then be injected into the space created by the air bubble to facilitate further separation of the layers. The deep stromal layers are excised, usually in quadrants (see Fig. 4.27.17). The intraoperative OCT can aid in determining dissection depth.<sup>18</sup> All viscoelastic material is removed to avoid a dual anterior chamber. A donor button, the same size as the trephination, is then placed after the removal of Descemet's membrane and the endothelium and secured using 10-0 nylon sutures.

**Fig. 4.27.14 The Lamellar Tissue Is Sutured to the Host Bed.** Suture placement is facilitated if the edge of the host bed is undermined. Traditionally, the graft is sutured with 10-0 nylon.

In femtosecond-assisted lamellar keratoplasty (FALK), the donor and recipient are cut with the femtosecond laser, and the donor lenticule can be placed without sutures on the recipient bed (Fig. 4.27.18). Only a bandage contact lens is used in cases when the residual stromal bed is thicker than 250 microns.<sup>11</sup>

### Complications and Postoperative Management

In general, anterior lamellar grafts can be very successful (see Figs. 4.27.15 and 4.27.16). Complications of ALK are less frequent or less severe in nature compared with those of PKP. Complications of lamellar graft include perforation of the recipient cornea, interface scarring and vascularization, persistent epithelial defect, inflammatory necrosis of the graft and graft melting, infection, astigmatism, and allograft rejection. Careful irrigation and cleaning of the host bed may reduce the incidence of complications. ALK has a significantly reduced incidence of allograft rejection because no transplantation of foreign endothelium is involved.

**Perforation of Descemet's Membrane.** This is a relatively common event early in the surgical learning curve. In small perforations, the case can proceed as planned, but the surgeon should leave a gas bubble (air or SF<sub>6</sub> 20%) in the eye to ensure that Descemet's membrane remains attached to the stroma. In larger perforations, a combination of gas and a pass-through suture may be necessary to anchor Descemet's membrane and avoid its retraction. In larger breaks, conversion to PKP may be required.

**Pseudo-Anterior Chamber.** A double anterior chamber may occur when an unrecognized Descemet's tear occurs, such as during suturing of the donor graft. Moreover, viscoelastic material has been implicated in certain cases. The dual chamber may resolve spontaneously, but most surgeons inject air or SF<sub>6</sub> 20% in the early postoperative period to enhance recovery times and potential endothelial cell loss.

### Triple Procedure (Combined Procedure)

A *triple procedure* or *combined procedure* refers to keratoplasty, combined with cataract extraction and IOL implantation.

### Preoperative Evaluation and Diagnostic Approach

The triple procedure is indicated for patients with a visually significant cataract who also require corneal transplantation for visual rehabilitation. Triple procedures are increasingly being performed with the use of the DSAEK or DMEK technique for patients with endothelial disease. If visualization permits, cataract extraction may be performed in a closed system by using standard phacoemulsification techniques. The leading indication for a triple procedure is Fuchs' endothelial dystrophy and cataract, which accounts for up to 77% of eyes that require a triple procedure.<sup>19-21</sup>

Compared with PKP, a combined procedure requires the additional calculation of the power of the IOL. Different formulas, such as the Holladay or the Sanders-Retzlaff-Kraff formula (Eq. 4.27.1),<sup>22</sup> in which A is the

(B) Air is released firmly and steadily forming a big bubble, in this case a type 1 bubble was formed. (C) A “brave slash” is performed to access the bubble. (D) Dissection of the anterior lamella is performed until Descemet’s membrane is exposed. (E) The endothelium is removed from the donor cornea, then the donor cap is sutured to the host. (F) Final result. (Courtesy Dr. F. A. Valenzuela.)

**Fig. 4.27.18 Femtosecond-Assisted Lamellar Keratoplasty (FALK).** (A) Residual granular dystrophy and central corneal scar seen in a patient after corneal transplantation. When the dystrophy recurred, phototherapeutic keratectomy (PTK) had been performed on the PTK, which eliminated some of the granular deposits but caused some corneal haze. (B) After FALK—FALK was performed to remove the corneal haze and residual anterior granular deposits. FALK (arrowheads) was centered over the visual axis, not over the corneal graft (arrows). (Courtesy Dr. C. L. Karp.)

constant for an IOL,  $AL$  is the axial length, and  $K$  is the keratometric measurement. The determination of  $K$  varies from surgeon to surgeon. The authors typically advocate one of two alternative approaches, using either the average of the surgeon’s past postoperative keratometric readings associated with the surgical technique or the  $K$  readings from the contralateral eye. In the instances in which an over- or undersized graft is required,  $+1.00$ – $+2.00$  diopters (D) is subtracted from the IOL power for a 0.5-mm oversized graft or  $+1.00$ – $+2.00$  D is added to the IOL power for 0.5-mm undersizing.<sup>16</sup> Postoperative refractive targets must be adjusted in DSAEK or DMEK triple procedures, as there may be a hyperopic shift associated with these procedures.<sup>23</sup>

$$\text{IOL power} = A - 2.5AL - 0.9K \quad [\text{Equation 4.27.1}]$$

### Surgical Techniques

**Open Sky Cataract Extraction.** The detailed surgical technique for PKP is described above. Prior to the trephination of the recipient cornea, trypan blue may be considered for visual augmentation of the capsulotomy. After the recipient button has been excised, a capsulorrhexis, sufficiently large to allow subsequent expression of the lens nucleus, is performed. Caution is maintained during the capsulorrhexis because there is a tendency for the capsulotomy to extend peripherally, especially with increased posterior pressure.

After hydrodissection and mobilization of the lens nucleus, the lens is gently expressed. The remaining cortical material is removed carefully using an automated irrigation–aspiration instrument or a manual I/A, as the anterior and posterior capsules tend to collapse toward each other. The capsular bag is then inflated with viscoelastic material, and the appropriate posterior chamber IOL is inserted. The authors of this chapter prefer a rigid or a three-piece IOL in this scenario for increased stability because of anterior chamber fluctuations. If a posterior capsular tear and anterior prolapse of vitreous occur, a limited anterior vitrectomy is performed, and the IOL is inserted either into the ciliary sulcus and sutured to the iris or sclera or an open-loop anterior chamber IOL may be used. The remainder of the procedure for PKP is the same as described previously.

### Artificial Cornea (Keratoprosthesis)

Keratoprosthesis implantation is performed in patients in whom corneal transplantation is considered high risk, with a very high likelihood of graft failure, such as those with a history of multiple graft failures or deep neovascularization of the cornea.

#### Boston K-Pro

The Boston Keratoprosthesis (K-Pro) (formerly known as the *Dohlman–Doane Kpro*) has been under development since the 1960s. It received Food and Drug Administration (FDA) approval for commercialization in 1992. It is the most commonly used keratoprosthesis in the world.<sup>23</sup> The

keratoprosthesis is made of clear polymethyl methacrylate (PMMA) plastic and has two pieces that take the shape of a collar button. The device is inserted into a corneal graft, which is then transplanted into the recipient's cloudy cornea. There are two types of the Boston K-Pro: (1) type I, available in phakic and pseudo-phakic versions, is used in patients with an adequate ocular surface, and (2) type II, which is placed through the lids in patients with severe ocular surface disease.

### AlphaCor

The AlphaCor implant, approved by the FDA in 2003, is made of a flexible hydrogel material similar to a soft contact lens. It contains a central clear zone that provides refractive power and a peripheral skirt or rim made of a special material that encourages the eye to heal over the device. The device is available in two powers: one for aphakic and one for phakic patients. The two-stage surgery involves the initial implantation of the AlphaCor device into the cornea of the recipient and the creation of a protective conjunctival flap over the prosthesis. The subsequent removal of the flap allows light to pass through the central clear zone to restore vision.<sup>24</sup>

A retroprosthetic membrane can occur following implantation of any artificial cornea and can be removed by using a YAG (neodymium-doped yttrium aluminum garnet) laser, unless highly vascular. Migration of the AlphaCor under the lamellar flap can occur.

### Modified Osteo-Odonto-Keratoprosthesis

The osteo-odonto-keratoprosthesis (OOKP) was first described in Italy and documented in 1963 by Benedetto Strampelli and later modified by Giancarlo Falcinelli et al. for the treatment of bilateral corneal blindness in patients with end-stage ocular surface disorders. Falcinelli's group has completed more than 220 cases, with an anatomical success rate of 94% and a mean follow-up of 9.4 years.<sup>25</sup> The first modified OOKP (MOOKP) was performed in the United States in 2009.

The newer MOOKP consists of a cylindrical PMMA lens embedded within the patient's own tissue (heterotopic autograft of the patient's tooth root and alveolar bone). The complete implantation is a three-stage procedure. Initially, the lens, iris, and vitreous are removed from the eye. A portion of the tooth (preferably canine), bone, and periodontal complex is concurrently resected, typically with the assistance of an oral maxillofacial surgeon, and shaped into a thin rectangular lamina. Some surgeons advocate the procurement of the bone lamina from the tibia. The PMMA lens is mounted into the center of the lamina, and the complex is placed into a subcutaneous pocket. After 1–2 months, a patch of buccal mucosa is obtained and sutured over the scarred and vascularized ocular surface. Alternatively, the first two stages may be performed simultaneously. After a minimum period of 3 months, the lamina is retrieved from the subcutaneous pocket. After trephining appropriately into both the cornea and oral mucosa for the cylindrical lens, the prosthesis is then secured to the surface of the eye between the layers of the scarred cornea and buccal mucosa using absorbable suture (Fig. 4.27.19).<sup>25</sup>

Like any other type of keratoprosthesis, patients after MOOKP require lifelong follow-up. Early in the postoperative period, a need exists for topical broad spectrum antibiotics. Once the mucosa is healed, there is no need for chronic topical antibiotic treatment. Multiple complications can occur after MOOKP, including glaucoma, which is the most common cause for loss of vision after MOOKP. For this reason, patients need IOP estimation (by finger palpation of the globe) and optic nerve head evaluation at every visit.

### Outcome

Corneal grafting techniques, such as PKP, ALK, and triple procedures, have become reliable and popular surgical techniques. Careful attention to preoperative evaluation, surgical techniques, and postoperative management will improve surgical outcome and patients' satisfaction.

## SUPERFICIAL CORNEAL PROCEDURES

### Historical Review

Superficial corneal procedures include corneal glue application (see Chapter 4.31), superficial keratectomy for anterior corneal degenerations and dystrophies, treatment of band keratopathy using ethylenediaminetetraacetic acid (EDTA; see Chapter 4.22), and corneal biopsy. With regard to superficial keratectomy for corneal dystrophies and other anterior pathologies, the advent of excimer laser phototherapeutic keratectomy (PTK) has become an effective alternative.

**Fig. 4.27.19 Modified Osteo-Odonto Keratoprosthesis (MOOKP).** Schematic drawing of the placement of the osteo-odonto-keratoprosthesis between the grafted buccal mucosa and the scarred and vascularized ocular surface. (Courtesy Sawatari S, Perez VL, Parel JM, et al. Oral and maxillofacial surgeons' role in the first successful modified osteo-odonto-keratoprosthesis performed in the United States. *J Oral Maxillofac Surg* 2011;69:1750–56, by kind permission.)

### Anesthesia

Superficial corneal procedures usually are performed under cover of topical anesthesia.

### Specific Techniques

#### Superficial Keratectomy

##### Preoperative Evaluation and Diagnostic Approach

Superficial keratectomy may be conducted either mechanically or with the excimer laser and consists of removal of pathological epithelial or subepithelial tissues. An AS-OCT may be helpful in delineating the depth of the corneal pathology. Indications include the following.<sup>17</sup>

- Anterior corneal dystrophies.
- Band keratopathy—often performed in conjunction with EDTA chelation.
- Superficial pannus or scar.
- Corneal dermoid, pterygium, or Salzmann's nodules.
- Excision of retained foreign bodies.

Superficial keratectomy also is used to obtain corneal tissue for microbiological or histological examination in the setting of infection or neoplasia.

#### Surgical Techniques

After the epithelium has been removed, the abnormal tissue is removed manually with a blade, a diamond burr, or the excimer laser. The corneal bed is left as smooth as possible. Bandage contact lenses or antibiotic ointment with a patch may be administered.

#### Complications and Postoperative Management

Bandage soft lenses, antibiotic drops, or aggressive lubrication should be continued until the corneal epithelium has healed. Oral analgesics are sometimes necessary to manage postoperative discomfort. Complications after superficial keratectomy include persistent epithelial defect, infection, and corneal scarring.

#### Corneal Biopsy

##### Preoperative Evaluation and Diagnostic Approach

Corneal biopsy is indicated in patients who have unresponsive and persistently culture-negative corneal ulcers.<sup>26</sup> Infections that arise from atypical mycobacteria, fungus, *Acanthamoeba*, and *Streptococcus viridans* with

**Fig. 4.27.20 Partial Trephination of the Cornea.** A 3-mm dermatological trephine is used to trephinate the cornea partially—both infected and noninfected cornea are straddled.

**Fig. 4.27.21** A blade is used to gently dissect the corneal tissue and removed with forceps.

associated crystalline keratopathy are examples of infectious disorders that may require corneal biopsy for definitive causative organism identification.

### Surgical Techniques

After topical anesthetic, a sterile, hand-held trephine (2–3 mm dermatological punch) is used at the slit lamp to achieve a partial-thickness trephination containing the pathological specimen. The size of the trephine depends on that of the lesion and the number of studies planned for the sample. The trephine is positioned to straddle the junction of diseased and normal corneal tissue (Fig. 4.27.20). After the partial-thickness trephination, the edge of the lesion, most easily in the area of healthy corneal tissue, is lifted using 0.12 forceps and dissected off the cornea using a blade (Fig. 4.27.21). The femtosecond laser also has been used to perform corneal biopsies.<sup>27</sup> The tissue is divided and sent for microbiological and histopathological evaluation.

### Complications and Postoperative Management

Complications can include perforation and postoperative secondary infection.

## Outcome

Eyes that undergo superficial corneal procedures, such as superficial keratectomy and corneal biopsy, generally heal well. The success of these techniques depends on the rate of re-epithelization and the underlying ocular surface pathology.

## PHOTOTHERAPEUTIC KERATECTOMY

The use of high-energy radiation of wavelength 193 nm is used to treat corneal pathology and smooth corneal surface irregularities. Laser energy emitted by the argon–fluoride (ArF) excimer laser for these purposes is referred to as PTK. The concept was first suggested by Trokel in 1983 and was approved by the FDA in 1995. PTK allows for the precise ablation of selected tissues in width and depth, leading to a regularization of the stromal bed. This can be used to treat anterior corneal pathology and thereby defer or eliminate the need for lamellar or penetrating keratoplasty.<sup>28</sup> Optimal results occur with pathology in the superficial 10%–20% of the cornea.<sup>29–33</sup>

## Preoperative Evaluation and Diagnostic Approach

Preoperative evaluation includes uncorrected visual acuity, best-corrected visual acuity by manifest refraction, hard contact lens refraction, pupil size measurements in ambient and near-dark lighting, slit-lamp biomicroscopy, dilated fundus examination, corneal topography, and wavefront analysis. The type of pathology and the proximity of the pathology to the pupillary center are documented, and the depth of pathology (as well as total corneal thickness) should be determined by AS-OCT. To plan the most effective procedure, determination of the pathology's ablation characteristics is necessary. The most common indications for PTK include recurrent erosion syndrome, anterior corneal dystrophies, superficial corneal scars, and Salzmann's nodules.<sup>29–32</sup>

Contraindications to PTK include severe keratoconjunctivitis sicca, uncontrolled uveitis, severe blepharitis, exposure keratopathy, and systemic immunosuppression. Moreover, PTK should be avoided in patients who have neurotrophic corneas (including previous herpes simplex or zoster keratitis or trigeminal nerve injury), collagen vascular disease, and diabetes because of potential problems with wound healing. Because of potential for microorganism spread during treatment, PTK should not be used for deep corneal scars or in active microbial keratitis, including infectious crystalline keratopathy.<sup>34,35</sup>

## Surgical Techniques

### Corneal Dystrophies, Scars, and Elevated Opacities

The goals of treatment of anterior stromal dystrophies are to ablate the confluent opacities in the visual axis and to remove the least amount of tissue possible to achieve the optimal visual outcome. Typically, the bulk of the lesions found in epithelial–stromal transforming growth factor- $\beta$ -induced dystrophies are located anteriorly (Fig. 4.27.22).<sup>36</sup> The middle and deep stroma often have fewer lesions with intervening clear stroma. Subsequently, deeper lesions are not ablated.<sup>37,38</sup>

Masking fluids are used to help fill in depressions and expose elevations of an irregular corneal surface by absorbing laser energy and thus shielding depressions. The most important principle is to use just enough masking fluid to cover the “valleys.” Carboxymethylcellulose 0.5% is of medium viscosity and efficiently covers the valleys and exposes the elevated areas. Methylcellulose 1%–2% is a high-viscosity fluid that may cover peaks, whereas hydroxypropylmethylcellulose 0.1% with dextran is of low viscosity and may leave valleys as well as peaks partly exposed.<sup>37</sup> It often is best to use more than one agent, depending on the particular corneal surface. Corneal dystrophies may recur after PTK. PTK may be repeated for recurrences even with previous grafts (Fig. 4.27.23). The success rate for recurrent granular corneal dystrophy type 1 or lattice dystrophy is extremely high and comparable with the high success rate for primary Reis–Bückler dystrophy, in which the deposits occur at Bowman's layer.<sup>28</sup> Macular corneal dystrophy and granular corneal dystrophy type 2 (formerly Avellino's dystrophy) have deeper lesions. Neither is usually amenable to PTK.

Elevated corneal opacities are often amenable to manual keratectomy with the use of a blade, which is efficacious when a suitable plane is found to leave a smooth surface on the cornea. When a plane cannot be found, it is possible to “debulk” the elevation and smooth the remaining area using the excimer laser. Alternatively, the epithelium may be removed from the

**Fig. 4.27.22 Granular Dystrophy.** (A) Preoperative anterior appearance of the opacities in a patient who has granular dystrophy. (B) The same eye 3 months after phototherapeutic keratectomy. (With permission from Salz JJ, McDonnell PJ, McDonald MB, editors. Corneal laser surgery. St Louis, MO: Mosby; 1995.)

area over the elevated lesion, and then photoablation performed to the underlying pathology, the surrounding epithelium is left in place to serve as a masking agent.<sup>29,31,32</sup>

### Postoperative Care

In the immediate postoperative period, a bandage soft contact lens is applied, and the patient is instructed to use broad-spectrum topical antibiotics. Topical corticosteroid, such as prednisolone acetate 1% or fluorometholone 0.1%, four times a day, is used and tapered to once daily within 1 month. Topical nonsteroidal anti-inflammatory drops may help control pain, which may be severe, so oral analgesics are frequently used.<sup>28,31,37</sup> Patients are examined every 24–72 hours until re-epithelization is complete, which generally occurs within 1 week.<sup>38</sup>

### Complications

#### Hyperopia

The most common side effect of PTK is induced hyperopia, which results from flattening of the central cornea. To avoid this problem, 1 diopter of hyperopic correction is added for every 14–20  $\mu\text{m}$  of PTK tissue ablation, performed at the time of treatment.<sup>39</sup>

#### Myopia/Myopic Astigmatism

Myopia and myopic astigmatism may be induced when the periphery or paracentral cornea undergoes a deeper ablation compared with the central cornea, and this may occur in the treatment of paracentral opacities.

**Fig. 4.27.23 Recurrent Granular Dystrophy in a Penetrating Keratoplasty.** (A) Preoperative appearance of the opacities in a patient with recurrent granular dystrophy in a penetrating keratoplasty. (B) Phototherapeutic keratectomy was performed and immediately postoperatively there was a dramatic reduction in the anterior stromal granules. (Bandage contact lens in place.) The patient ultimately developed haze and required a femtosecond-assisted lamellar keratoplasty. (Courtesy Dr. C. L. Karp.)

### Irregular Astigmatism and Decentration

Irregular astigmatism is an undesirable potential outcome that may be minimized by using masking agents to help achieve a smooth corneal contour postoperatively. Decentration may also lead to irregular astigmatism.

#### Pain

Pain may be severe after excimer laser photoablation. Judicious use of topical corticosteroids, nonsteroidal anti-inflammatory agents, chilled balanced salt solution, and oral pain medication has helped in pain control after excimer laser treatment.<sup>40</sup>

### Delayed Epithelization

Epithelial healing is usually complete within the first week. Delayed epithelial healing puts the patient at risk for infection and haze. Persistent epithelial defects or recurrent erosions may be more common in patients who have preoperative DED, herpes simplex virus infection, or diabetes. Bandage contact lenses and lubrication are helpful in the promotion of epithelial healing.<sup>28</sup> Punctal plugs often are useful in patients who have signs or symptoms of DED. The use of blood derivatives or a temporary tarsorrhaphy may be considered in recalcitrant cases.

### Bacterial Keratitis

Bacterial keratitis is a feared postoperative complication because of the presence of an epithelial defect and the placement of a contact lens on what may be an already compromised cornea. Most surgeons performing PTK believe the ability of bandage contact lenses to decrease pain and help epithelial wound healing outweighs the risk of bacterial keratitis. Prophylactic antibiotic drops are used postoperatively. Stromal infiltrates are managed similarly as in patients who have had photorefractive keratectomy. Non-steroidal anti-inflammatory agents, contact lenses, and infectious keratitis may lead to infiltrates.<sup>32,41</sup>

### Viral Keratitis

Herpes simplex virus may be reactivated after PTK. Treatment of patients who have a history of herpes is controversial. In cases that are treated, a prophylactic regimen of preoperative and postoperative oral antiviral therapy is given.

### Recurrence and Haze

Corneal dystrophies treated with PTK may recur. Retreatment may be performed, although the possibilities of increased hyperopia and anisometropia must be considered. Furthermore, haze often results after PTK and may be confluent and visually significant. Haze results from the presence of activated keratocytes and their products (newly formed collagen and proteoglycans in an irregular network).<sup>30,42,43</sup> Haze often decreases over time, and a period of 12 months is allowed to elapse before the haze is treated. The intraoperative use of mitomycin C has reduced the likelihood of haze and scarring and improved visual outcomes.<sup>44</sup>

### Graft Rejection

Corneal graft rejection in PTK-treated patients has been reported, as in Hersch et al.<sup>45</sup> for recurrent lattice dystrophy and others for postoperative

astigmatism.<sup>42</sup> Medical treatment of the rejection episodes have been reported as successful.

## Outcome

The 193 nm ArF excimer laser is an excellent tool in the treatment of anterior corneal pathology and surface irregularities. The expense and risks associated with penetrating keratoplasty, including the risks of intraocular surgery and anesthesia, may be avoided. Treatment must be individualized on the basis of the type of pathology and its ablation characteristics and depth.

# Conjunctival Surgery

Victoria S. Chang, Carolina L. Mercado, Ibrahim O. Sayed-Ahmed, Allister Gibbons, Carol L. Karp

# 4.28

**Definition:** Conjunctival procedures may be used to cover an unstable or painful corneal surface or to remove pterygia or other abnormal growths.

## Key Features

- Careful preoperative planning is critical for success.
- It is important to have a clear understanding of intraoperative and postoperative complications and management.

## Associated Feature

- Recurrences of pterygium may be more aggressive than initial pterygium.

## HISTORICAL REVIEW

Conjunctival procedures include a bridge conjunctival flap (Gundersen flap),<sup>1,2</sup> pterygium surgery, conjunctival excision for conjunctivochalasis, limbal stem cell transplantation (see Chapter 4.30), and tumor removal. In a conjunctival flap procedure, a hinged flap of conjunctiva is created to cover an unstable or painful corneal surface. Conjunctival flaps, partial or total, have remained an effective procedure over the past 100 years for the treatment of challenging ocular surface disorders in patients with poor visual prognosis.

Pterygium surgery dates back to 1855, when Desmarres<sup>3</sup> first performed a transposition of the pterygium head. In 1872, Arlt recognized the importance of covering the epibulbar defect after pterygium excision and described the first conjunctival graft.<sup>4</sup>

## ANESTHESIA

Conjunctival surgeries typically are performed under cover of local, retrobulbar, infiltrative, or (rarely) general anesthesia. To prevent squeezing during surgery, a lid block is sometimes employed. General anesthesia is reserved for pediatric patients and uncooperative adults.

## SPECIFIC TECHNIQUES

### Conjunctival Flap

#### Preoperative Evaluation and Diagnostic Approach

Common indications for conjunctival flap include the following:

- Nonhealing sterile corneal ulcerations secondary to chemical or thermal injuries, herpetic infections, exposure keratopathies, and other neurotrophic diseases that are unresponsive to medical treatment.
- Painful bullous keratopathy or other chronically inflamed ocular surface disorders in eyes with low visual potential, in which penetrating or selective keratoplasty is not indicated; and in which simpler management techniques, such as soft contact lenses or anterior stromal puncture, have failed.
- Necrotizing scleritis resulting in severe melt that is unresponsive to systemic anti-inflammatory treatments, requiring tectonic support.
- Blind eyes in need of surface preparation for prosthetic shells or cosmetic contact lenses.

**Fig. 4.28.1 360° Peritomy.** Westcott scissors are used. The dissection is carried out toward the corneal limbus with care not to buttonhole the conjunctiva. (Courtesy Dr. R. K. Forster.)

Relative contraindications for conjunctival flap include active infectious keratitis and corneal perforation in eyes with good visual potential.

### Surgical Techniques

The availability of mobile conjunctiva is evaluated. Typically, the superior bulbar conjunctiva offers increased tissue availability. The corneal epithelium is mechanically debrided using a No. 64 blade or a cellulose sponge. Application of lidocaine 4% or absolute alcohol may assist in loosening the corneal epithelium. A 360° limbal peritomy is then performed (Fig. 4.28.1).

The globe is rotated inferiorly from the donor site using a traction suture placed at the limbus to increase superior exposure. A semicircular incision, parallel to the corneal limbus, is made as posteriorly as possible. The dissection of a thin conjunctival flap is carried anteriorly until the corneal limbus is reached. Adequate dissection and undermining of this flap laterally is important for the subsequent anterior mobilization of the flap over the cornea and to prevent traction. The conjunctival flap is freed completely from its underlying Tenon's capsule.

The well-mobilized conjunctival flap then is stretched to cover the desired area (Fig. 4.28.2). The superior and inferior aspects of the flap are secured on the sclera using interrupted or running 10-0 nylon sutures. The edges of the conjunctiva may be reapposed with 7-0 or 8-0 Vicryl suture in a running fashion (Fig. 4.28.3). Alternatively, fibrin glue has been shown to be a viable option for Gundersen flap surgery, with the possible advantage of reduced surgical and recovery time.<sup>5</sup>

A partial conjunctival flap is used in certain circumstances, such as for focal nonhealing corneal ulcers that do not require coverage of the entire cornea. The procedure includes scraping of the corneal epithelium, mobilization of the conjunctiva in the appropriate quadrant, and suturing of the conjunctival flap over the localized corneal defect (see Fig. 4.28.3).

A total Tenon-conjunctival flap (TCF) has been used to increase corneal thickness in mildly phthisical eyes in preparation for prosthetic scleral shells.<sup>6</sup> A modified Gundersen flap with the use of amniotic membrane transplantation has been reported in a small series of patients as a promising technique.<sup>7</sup>

**Fig. 4.28.2** Mobilization of the conjunctival flap to the desired area of the cornea. (Courtesy Dr. R. K. Forster.)

**Fig. 4.28.3** Conjunctival Flap Over a Sterile Ulcer. The flap is sutured into position with 10-0 nylon sutures superiorly and 7-0 Vicryl sutures through the inferior limbal episclera. (Courtesy Dr. R. K. Forster.)

### Complications and Postoperative Management

The most common perioperative complication is the creation of a conjunctival buttonhole during dissection. Buttonholes should be closed by using running or interrupted sutures. Postoperative complications include retraction of the conjunctival flap, hemorrhagic and epithelial mucous cysts, flap loss from epithelial ingrowth, ptosis, and progression or recurrence of inflammation or infection, such as that caused by herpes simplex virus.<sup>8,9</sup>

After healing, a cosmetic contact lens may be fitted. In some cases, penetrating keratoplasty is indicated for visual rehabilitation. Because a conjunctival flap may have destroyed corneal limbal stem cells, a limbal allograft may be considered prior to penetrating keratoplasty.

### Pterygium Surgery

Pterygium, most commonly seen at the nasal limbus, is a conjunctival fibrovascular growth over the sclera and onto the cornea (see Chapter 4.9 for more information).

### Preoperative Evaluation and Diagnostic Approach

Surgical indications for excision of the pterygium include the following:

- Growth of pterygium such that it has impinged on or is imminently threatening the visual axis.
- Reduced vision as a result of induced astigmatism.

**Fig. 4.28.4** Dissection of the Head of the Pterygium From the Cornea. A blade is used.

**Fig. 4.28.5** Removal of the Body of the Pterygium. Westcott scissors are used with care to avoid damage to the underlying rectus muscle.

- Severe irritation not relieved by medical therapy.
- Surgery for unacceptable cosmetic appearance.
- Reduced motility secondary to pterygium.
- Recurrence, with more aggressive growth than in primary lesions.

### Surgical Techniques

Several techniques have been described including bare sclera technique, conjunctival autograft placement, amniotic membrane transplantation, antimetabolites, radiation, and, in cases of severe recurrence, mucous membrane grafts.

### Bare Sclera Technique/Simple Closure

Although technically simple, this technique can be associated with recurrence rates as high as 40%.<sup>9</sup> Surgically, the lesion may be outlined using spot cautery or a sterile marker. To facilitate dissection, the eye may be rotated laterally using traction sutures (6-0 Vicryl or silk) placed at the superior and inferior corneal limbus. The dissection may be initiated at the corneal side of the pterygium. Using forceps, the head of the pterygium is lifted and dissected off the cornea in a lamellar fashion using sharp dissection with a blade (Fig. 4.28.4). Alternatively, the scleral portion may be removed first, followed by blunt dissection or avulsion of the corneal portion. The scleral part of the pterygium is excised by using scissors (Fig. 4.28.5). Care is taken to identify the underlying rectus muscle, especially in surgery for recurrent pterygium. The corneal defect may be polished by using a diamond burr. Antimetabolite agents, such as mitomycin-C (MMC) 0.02%, have been used to prevent recurrence in conjunction with this technique. Care should be taken to avoid excessive contact of MMC with the sclera. Instead of leaving the sclera bare, the conjunctiva can be closed

**Fig. 4.28.6 Dissection of the Conjunctival Graft.** The limbus is marked and the healthy conjunctiva is harvested. The conjunctiva is dissected gently with care not to buttonhole the donor tissue.

**Fig. 4.28.7 Conjunctival Autograft in Position Over the Previously Excised Pterygium.** Two 10-0 nylon sutures are placed at the limbus and 8-0 Vicryl sutures are used along the conjunctiva in an interrupted fashion. Care is taken to maintain the limbus-to-limbus position of the graft.

with 7-0 or 8-0 Vicryl suture, although the recurrence rates have not been shown to be significantly reduced with primary closure.<sup>10,11</sup>

### Autograft

Conjunctival autografting is considered the “gold standard” for pterygium surgery because of its low rate of recurrence (rates reported as low as 5% in primary cases) and excellent cosmesis.<sup>9</sup> After pterygium excision, the size of the defect is measured. Commonly, in a nasal pterygium, the superotemporal bulbar conjunctiva is used as the donor site. Tractional sutures may be used to rotate the eye downward. The donor conjunctiva is outlined using spot cautery or a sterile marker and a thin Tenon’s free conjunctival flap is dissected with forceps and scissors (Fig. 4.28.6). It is important to avoid buttonholes and to maintain limbus-to-limbus orientation of the conjunctival flap when transferring the flap to the recipient bed to ensure proper positioning of limbal stem cells. Alternatively, the conjunctival flap may be rotated on a pedicle. The graft is then secured using Vicryl or 10-0 nylon sutures (Fig. 4.28.7), or fibrin glue.

### Amniotic Membrane

Amniotic membrane transplantation (AMT) has been implemented as an alternative to conjunctival autografting despite its higher cost. Amniotic

**Fig. 4.28.8 Corneoscleral melt** after pterygium excision associated with the use of radiation.

membranes are secured using similar techniques as conjunctival autografts and are especially amenable to the use of fibrin glue. The amniotic membrane is placed stromal side adjacent to the scleral bed. Benefits include shortened operative time and untouched conjunctiva for future use, such as in glaucoma surgery. However, in a prospective study (mean follow-up, 11 months) comparing AMT to conjunctival autografts, AMT had higher recurrence rates for primary (10.9% versus 2.6%), recurrent (37.5% versus 9.1%), and all pterygia (14.8% versus 4.9%) compared with conjunctival autografts, respectively.<sup>10</sup> These results establish the use of conjunctival autografting as the procedure of choice for pterygium surgery unless a conjunctival preserving technique is indicated.

**Other Techniques.** Several, more recent techniques have been described to have success in preventing pterygium recurrence after excision. Limbal conjunctival autograft (LCAU), in which a free conjunctival graft is harvested to include the superficial limbus, has been demonstrated to have a low recurrence rate (6.9%) after 10 years of follow-up.<sup>12</sup> Minor ipsilateral simple limbal epithelial transplantation (mini-SLET), which utilizes amniotic membrane and the placement of limbal epithelial pieces, has been described in the treatment of 10 eyes without recurrence after 8 months of follow-up.<sup>13</sup>

**Recurrent Pterygium Excision.** Excision of recurrent pterygia can be especially tedious even for the experienced surgeon because of extensive fibrosis of the pterygium to the sclera and cornea, distortion of tissue planes and normal anatomy, and symblepharon formation. The rectus muscle should be isolated in cases of scarring of the muscle sheath prior to dissection, and all symblepharon must be released to alleviate any motility restriction.

### Antimetabolites and Radiation

MMC has been used preoperatively, intraoperatively, and postoperatively in pterygium surgery and appears to reduce the recurrence rates (particularly if amniotic membrane is used). Antimetabolites, however, have been associated with serious complications, including corneal or scleral melts. Thus, MMC should be used judiciously in cases with a high likelihood of recurrence. In addition, beta radiation using strontium-90 has been employed and shown to reduce recurrence; however, it may cause significant complications such as scleral necrosis, cataract, and persistent epithelial defects (Fig. 4.28.8). Beta radiation after pterygium surgery has been supplanted largely by conjunctival or amniotic membrane transplantation.

### Fibrin Glue

Fibrin glue is a two-component tissue adhesive that is used in many surgical procedures. One component consists of a protein fibrinogen solution, and the other consists of a thrombin solution. When mixed together, a fibrin clot is formed. Several studies have shown that the use of fibrin glue decreases postoperative pain and foreign body sensation and leads to reduced operative time and blood loss during surgery.<sup>14,15</sup> It is being used with increasing frequency with both conjunctival autografts and amniotic membranes. Additionally, fibrin glue eliminates or reduces the number of sutures required. In a recent study, comparing Vicryl sutures to two of the most commonly used fibrin glues worldwide, Tisseel (Baxter Corp., Deerfield, IL) and Evicel glue (Omrix Biopharmaceuticals Ltd., Ramat-Gan, Israel), Tisseel glue was found to be superior with regard to pterygium

**Fig. 4.28.9 Thermocautery of Inferior Conjunctivochalasis.** Excess conjunctiva is grasped with smooth forceps approximately 5 mm from the limbus and then cauterized with a handheld cautery.

recurrence, patient comfort, and surgical time.<sup>16</sup> Patients must understand that this is an off-label use for fibrin glue. Patients also need to give their consent for blood product use because fibrin glue is derived from pooled human blood. However, it has been used for many years in thousands of surgeries with no documented cases of transmission of hepatitis B or C, human immunodeficiency virus (HIV) infection, or prion-mediated disease. Furthermore, donated plasma undergoes viral polymerase chain reaction screening prior to use.

### Complications and Postoperative Management

Complications of pterygium surgery include recurrence of the pterygium, conjunctival granuloma, subconjunctival hemorrhage, corneoscleral dellen, epithelial inclusion cysts, graft retraction or necrosis, corneal or scleral melt with the use of antimetabolites or beta radiation, and conjunctival fibrosis. Topical antibiotics and corticosteroids are prescribed after surgery. Topical corticosteroids generally are used for 1–2 months postoperatively to minimize resultant inflammation.

## Conjunctivochalasis Management

Conjunctivochalasis is a loosely adherent, redundant conjunctiva more commonly found overlying the inferior bulbar surface, typically in older individuals or those with a history of chronic inflammation. Although often asymptomatic, it may interfere with normal tear flow, lubrication of the ocular surface, and cause local exposure and associated irritation or pain. Additionally, if prominent nasally, the redundant conjunctiva may occlude the lower punctum, resulting in epiphora. In patients with significant symptoms uncontrolled with topical medications, such as artificial tears and topical corticosteroids, conjunctival cautery and surgical excision have been proposed as treatment modalities. These options must be approached judiciously, as the condition is likely to recur. Simple cauterization of the conjunctiva is usually performed in the office after topical gel anesthetic is applied using smooth forceps to grasp the excess inferior conjunctiva several millimeters from the limbus, which is then cauterized (Fig. 4.28.9). Additional options include conjunctival resection (Fig. 4.28.10) and scleral fixation of the conjunctiva. Surgical consideration should be given only when conservative treatment modalities are insufficient in providing adequate relief.

**Fig. 4.28.10 Conjunctival Resection for Symptomatic Inferior Conjunctivochalasis.** Wescott scissors and smooth forceps are used to excise the marked crescent of excess conjunctival tissue.

### Surgical Techniques

After topical anesthesia is instilled, smooth forceps are used to grasp the excess inferior conjunctiva approximately 5 mm from the limbus, which is then marked with a marking pen. Using Wescott scissors and smooth forceps, the marked crescent of conjunctival tissue is then excised (see Fig. 4.28.10). Vicryl sutures are then used for simple closure of the conjunctiva, or an amniotic membrane transplant can be sutured or glued over the defect.

### Complications

Recurrence of conjunctivochalasis after simple cautery or even excision should be discussed with the patient prior to the procedure. Other complications that may arise after conjunctival excision include conjunctival fibrosis, subconjunctival hemorrhage, granuloma formation, and cicatricial entropion.

# Endothelial Keratoplasty: Targeted Treatment for Corneal Endothelial Dysfunction

Marianne O. Price, Francis W. Price, Jr.

# 4.29

IN THIS CHAPTER  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Endothelial keratoplasty has significant advantages over penetrating keratoplasty as a targeted method to replace endothelial cells in the treatment of endothelial dysfunction.

## Key Feature

- Targeted replacement of corneal endothelium through a small 2–5 mm incision.

## Associated Features

- Rapid visual recovery.
- Few activity restrictions.
- No significant increase in astigmatism.
- Minimal disruption of corneal innervation.
- Lower risk of immunological rejection than with penetrating keratoplasty.
- Rapid sequential surgery.

## INTRODUCTION

Penetrating keratoplasty (PKP) was long considered the gold standard for the treatment of endothelial dysfunction. Advances in endothelial keratoplasty (EKP) techniques, coupled with the many advantages it offers to patients, have made it the preferred treatment for endothelial dysfunction (Fig. 4.29.1).

After PKP, it generally takes 6 months to several years for the refraction to stabilize<sup>1–3</sup>; 10%–15% of the patients typically require a hard contact lens for best vision<sup>4,5</sup>; and a final mean refractive cylinder of 4–5 D is common.<sup>3,5</sup> Furthermore, PKP incision severs all corneal nerves, so the inclination to blink and produce tears is reduced postoperatively. This, together with the prolonged presence of corneal sutures to hold the graft in place, increases the risk that ocular surface complications will interfere with recovery.<sup>6,7</sup> Moreover, because of the PKP wound, the cornea never regains the full strength of a virgin cornea, so an eye that has undergone PKP is forever at increased risk of loss from a traumatic injury.<sup>8</sup>

In contrast, EKP involves selective removal of dysfunctional recipient corneal endothelium and replacement with donor tissue consisting of healthy endothelium, with or without posterior stroma.<sup>9</sup> EKP is performed through a small incision and spares the majority of the host cornea, so corneal strength and surface topography are minimally altered, and the technique is essentially refractive-neutral.<sup>10–13</sup> Furthermore, corneal innervation is retained, and corneal sutures are not required, so ocular surface complications are minimal.<sup>14</sup> Finally, the small incision allows rapid healing and visual recovery, and patients can resume normal activities within weeks of surgery.

## EVOLUTION OF EKP TECHNIQUES

Originally described by Tillett in 1956,<sup>15</sup> EKP has evolved rapidly, particularly since 1998, when Melles reported successful replacement of dysfunctional endothelium through a scleral–limbal approach, using an air bubble

rather than sutures to secure the donor tissue, in a technique he called *posterior lamellar keratoplasty* (PLK).<sup>16</sup> Later renamed *deep lamellar endothelial keratoplasty* (DLEK), this technique required lamellar dissection of the recipient and donor corneal tissue. Both dissections were originally done manually by using a series of curved blades of increasing length.

Melles subsequently eliminated the challenging recipient stromal dissection and excision steps by peeling the Descemet's membrane (DM) and dysfunctional endothelium from the recipient cornea before implanting the donor tissue.<sup>17</sup> This EKP modification became known as Descemet's stripping with endothelial keratoplasty (DSEK).<sup>10,13</sup> Use of a microkeratome was introduced to facilitate the donor lamellar dissection,<sup>12,18</sup> and this technique variation was referred to as either DSEK or Descemet's stripping automated endothelial keratoplasty (DSAEK). In 2005, eye banks began performing the donor lamellar dissection with a microkeratome and providing “precut” tissue to surgeons.<sup>19</sup>

Even though DSEK provides 20/40 or better vision more reliably compared with PKP, fewer patients than expected achieve 20/20 vision, and variations in the donor stromal thickness increase the higher order aberrations of the posterior corneal surface.<sup>20</sup> Over time, surgeons have gravitated toward use of thinner DSEK tissue, which seems to provide better vision with less risk of rejection than thicker tissue,<sup>21</sup> although the rate of tissue loss is greater with ultra-thin DSEK.

Aiming for exact anatomical replacement with the thinnest possible tissue, Melles developed a technique for peeling DM and healthy endothelium from a donor cornea and implanting it into a recipient eye in a method he called DM endothelial keratoplasty (DMEK).<sup>22</sup> The extremely thin DMEK graft is more challenging to handle compared with a thicker DSEK graft (Fig. 4.29.2), leading to the development of hybrid techniques with a narrow rim of donor stromal tissue ringing a central area of bare endothelium without stroma. The hybrid techniques, known as DMEK-S and DMAEK, were not widely adopted because the risk of tissue loss was greater than with DMEK.<sup>23,24</sup>

A variation of DMEK, called pre-Descemet's endothelial keratoplasty (PDEK), utilizes a big bubble to separate the donor Descemet's membrane and endothelium from the donor stroma.<sup>25</sup> With a type 1 big bubble, a pre-Descemet's layer remains attached to Descemet's membrane, thereby providing slightly thicker tissue than in standard DMEK. This results in easier unfolding and the ability to utilize tissue from younger donors who have a thinner Descemet's membrane. The disadvantages of PDEK are that the graft diameter is limited by the big bubble diameter to about 7–75 mm and the donor tissue must be cut from the underlying stroma with scissors. Time will tell which of these technique variations become dominant for standard noncomplicated cases, such as Fuchs' dystrophy.

## INDICATIONS

EKP is an excellent option for any type of endothelial dysfunction (Box 4.29.1).<sup>9,13,24–26</sup> With appropriate modifications, EKP can be performed in eyes with peripheral anterior synechiae, glaucoma filtration surgery, and iris abnormalities, including aniridia.<sup>26–28</sup> If anterior stromal scarring from long-standing corneal edema is significant, replacement of the full corneal thickness with a PKP may provide better visual acuity. However, in many cases, patients who have tolerated long-standing corneal edema also have other visual limitations (e.g., retinal problems). In such cases, EKP is an attractive alternative because it quickly resolves the corneal edema and

**Fig. 4.29.1** Slit-lamp images of penetrating keratoplasty (A) and Descemet's membrane endothelial keratoplasty (C), with corresponding anterior segment optical coherence tomography images (B,D). (A,B from Anshu A, Price MO, Tan DTH, et al. Endothelial keratoplasty: a revolution in evolution. *Surv Ophthalmol* 2012;57:236–52, Fig. 1.)

bullae while maintaining much of the structural integrity of the eye. In eyes with significant iris defects, aniridia, and/or aphakia, DSEK is preferable to DMEK, which can more easily escape into the posterior chamber or be damaged by contact with an intraocular lens (IOL) or artificial iris during unfolding.

## SURGICAL TECHNIQUE

### Anesthesia and Recipient Preparation

EKP is readily performed with topical or local anesthesia. With local anesthesia (using a retrobulbar or peribulbar block), it is important to ensure

#### PRINCIPAL EK TECHNIQUES

**Fig. 4.29.2** Diagram illustrating the differences between Descemet's stripping endothelial keratoplasty (DSEK) and Descemet's membrane endothelial keratoplasty (DMEK). The host cornea epithelial and endothelial layers are depicted in sky blue, the host stroma in pale blue, the donor endothelium in dark blue, and the donor stroma in medium blue.

#### BOX 4.29.1 Endothelial Keratoplasty: Indications and Contraindications

##### Indications

- Essentially all forms of endothelial dysfunction
- Fuchs' endothelial dystrophy
- Pseudo-phakic or aphakic bullous keratopathy
- Previous failed penetrating keratoplasty
- Posterior polymorphous dystrophy
- Congenital hereditary endothelial dystrophy
- Iridocorneal endothelial (ICE) syndrome
- Endothelial failure from trauma, previous surgery, angle closure or glaucoma drainage devices

##### Contraindications

- Advanced keratoconus and anterior stromal dystrophies
- Hypotony
- Stromal opacities that would preclude acceptable postoperative vision

that there is no back pressure from periorbital swelling because back pressure can cause the anterior chamber to forcefully shallow while the donor tissue is being inserted and may even push the donor tissue back out of the eye.

A 2–5 mm clear corneal or scleral tunnel incision is made in the recipient eye. Temporal placement of the incision has several advantages compared with superior placement: Donor button insertion is facilitated because the corneal diameter is longer horizontally; the superior conjunctiva is preserved for future glaucoma surgery, if needed; and orbital anatomy, such as large brows or sunken globes, is not as important.<sup>10</sup> If the recipient epithelium is hazy or scarred, it can be removed, generally improving the view into the eye.

If the host Descemet's membrane has any guttae or other abnormalities, then it should be removed before implanting the donor tissue for optimal visual results. The anterior chamber is filled with air or viscoelastic to facilitate visualization of DM during its removal. A blunt Sinskey hook is used to score DM in a circular pattern to outline the area of planned membrane removal.<sup>10</sup> The far edge of DM is grasped with a stripping instrument or infusion/aspiration tip and carefully is peeled off and removed from the eye (Fig. 4.29.3).<sup>17</sup> Trypan blue can be injected into the anterior chamber immediately after stripping DM to facilitate visualization of loose pieces of Descemet's membrane or stroma.<sup>14</sup> After the membrane is removed, it can be spread on the surface of the cornea to determine whether removal was complete or whether some fragment might remain in the eye. If viscoelastic material was used, care should be taken to completely remove it from the anterior chamber and back surface of the cornea because retained viscoelastic material on the stromal surface can impede attachment of the donor tissue and impair vision.<sup>29</sup>

**Fig. 4.29.3** Stripping of host Descemet's membrane using a 90° angled stripper.

**Fig. 4.29.5** Air injection to lift and press the donor tissue up against the host cornea.

**Fig. 4.29.4** Lamellar dissection of the donor tissue with a microkeratome in Descemet's stripping endothelial keratoplasty (DSEK).

**Fig. 4.29.6** Massaging the surface of the recipient cornea to center the Descemet's stripping endothelial keratoplasty (DSEK) donor tissue and remove fluid from the donor/recipient interface, while the anterior chamber is completely filled with air.

## Donor Tissue Preparation and Insertion

Donor tissue preparation involves three steps: dissection; sizing to the appropriate diameter with a trephine (usually 8–9 mm); and insertion. Preparing the donor tissue before opening the patient's eye allows the surgeon to ensure that the tissue will be suitable for transplantation.

### *Descemet's Stripping With Endothelial Keratoplasty*

The lamellar dissection usually is done with a microkeratome either at the eye bank or at the time of surgery (Fig. 4.29.4).<sup>19</sup> A donor corneal/scleral shell is mounted on an artificial anterior chamber designed to accompany the microkeratome being used. The artificial anterior chamber can be filled with viscoelastic material, balanced salt solution, or tissue storage solution. The donor thickness is measured, and a microkeratome head of appropriate depth is selected to provide a posterior donor button of approximately 0.08–0.15 mm thickness, according to the surgeon's preference.

The donor tissue is carefully transferred from the artificial anterior chamber and placed endothelial side up on a standard punch trephine block, where it is punched to an appropriate diameter, taking into consideration the horizontal white-to-white dimensions of the recipient cornea and the anterior chamber depth. The donor tissue is covered with tissue storage solution while the recipient eye is prepared.

A variety of insertion techniques are available, including forceps, glides, and inserters.<sup>10,11,30–33</sup> When using forceps, the posterior donor button is folded over on itself like a “taco” with approximately 60% anterior and 40% posterior, and the folded tissue is gently grasped at the leading edge with forceps that only compress at the tip as the tissue is guided into the eye. A disadvantage of this method is that it can be difficult to unfold the donor correctly in the eye, especially for surgeons early in the learning curve. Another method is to fixate the edge of the donor with a suture, thread the

suture across the anterior chamber and out through a stab incision nasally, and pull the tissue into the eye.<sup>30</sup>

A third method is to place the tissue on a glide or insertion cartridge, insert retina/vitreous intraocular forceps through a nasal stab incision, reach across the eye and grasp the tip of the donor through the 5-mm temporal incision, and pull the tissue into the eye (Video 4.29.1).<sup>31–33</sup> The tissue also can be inserted with a single-use inserter. Use of a funnel glide or inserter helps the donor tissue curl with the endothelium inward for protection as it is inserted.<sup>32,33</sup>

Once the donor tissue is in the eye and unfolded stromal side up, the anterior chamber is filled with air to press the donor button up against the recipient cornea (Fig. 4.29.5). While the anterior chamber is completely filled with air, a LASIK (laser-assisted in situ keratomileusis) roller can be used to help center the donor tissue and massage fluid out of the donor/recipient interface (Fig. 4.29.6).<sup>14</sup> Several small incisions can be made in the peripheral recipient cornea down to the graft interface to help drain any fluid trapped between the donor and recipient tissue.<sup>14</sup> Intraoperative optical coherence tomography (OCT) can help identify fluid in the interface. After 8–10 minutes, many surgeons remove most of the air to prevent pupillary block, and leave the anterior chamber approximately one third full. Some surgeons then have the patients lay face up with a partial air bubble for 30–60 minutes. Other surgeons leave the anterior chamber completely filled for 1–2 hours. At the completion of surgery, antibiotics, corticosteroids, dilating drops, and nonsteroidal anti-inflammatory drugs (NSAIDs) are applied to the treated eye.

### *Descemet's Membrane Endothelial Keratoplasty*

The most common donor tissue dissection technique consists of gently peeling off DM and endothelium (Video 4.29.2).<sup>34–37</sup> First, the DM periphery

See clip:  
4.29.1

See clip:  
4.29.2

**Fig. 4.29.7 Descemet's Membrane Endothelial Keratoplasty (DMEK) Donor Tissue Preparation.** A nontoothed forceps is being used to peel Descemet's membrane and endothelium from a donor corneal/scleral rim that is submerged in corneal storage solution in a cornea viewing chamber. The corneal/scleral rim was stained with trypan blue to enhance visualization of the scored edge of the membrane.

is scored all the way around. The tissue is stained with trypan blue to enhance visualization. The peripheral edge is lifted all the way around by using a microfinger or hockey stick-shaped instrument. With the tissue submerged in tissue storage solution, an edge of the membrane is grasped with forceps and peeled about halfway to the center, quadrant by quadrant, with replacement of each section on the stromal base (Fig. 4.29.7). The tissue is partially trephined, cutting through DM but not completely through the stroma. An edge is grasped with nontoothed forceps, and the central DM is gently peeled from the underlying stroma and replaced in tissue storage solution. Donor DM and endothelium also can be isolated using air, fluid, or viscoelastic.<sup>23–25</sup> However, using a type 1 big bubble to detach DM limits the graft diameter to about 7–7.5 mm, and the graft must be cut from the stroma with scissors.

See clip:  
4.29.3

Immediately before insertion into the recipient eye (Video 4.29.3), the donor tissue is stained again with trypan blue to improve visualization. The donor tissue naturally curls up endothelium-outward and can be placed in a glass pipette or inserter, such as an IOL injector, for placement in the recipient eye. The donor DM is gently unfolded in the correct orientation with a combination of balanced salt solution and air injections. Then air or a long-acting gas (20% sulfur hexafluoride) is injected beneath the donor tissue to completely fill the anterior chamber and press the graft up against the host cornea.

Instead of allowing the donor tissue to naturally curl with the endothelium facing outward, opposite sides can be folded over the middle (trifold technique), with the endothelium facing inward.<sup>38</sup> The folded tissue is pulled into an IOL cartridge and injected into the eye or pulled in with forceps. Both the PDEK donor preparation method and the trifold DMEK insertion technique facilitate unfolding the donor tissue inside the recipient eye. Thus both allow use of younger donor tissue, which otherwise can be more challenging to unfold.

## COMBINED PROCEDURES

EKP can be combined with other intraocular surgeries, such as phacoemulsification, IOL implantation, IOL exchange, secondary lens implant, pars plana vitrectomy, or anterior vitrectomy.<sup>13,14</sup> Combining EKP with surgeries that require a larger incision can complicate wound closure and maintenance of an air-tight incision, which is important for ensuring donor attachment. A modest mean hyperopic shift typically is reported after EKP (in the range of 0.25–0.5 D after DMEK and 0.5–1.5 D after DSEK).<sup>9,13,35</sup> Therefore, when cataract extraction and IOL implantation is performed before EKP, whether as a staged or combined procedure, the expected refractive shift should be factored into the IOL calculation.

## OUTCOMES

### Visual Acuity

EKP provides more rapid and predictable visual recovery than PKP, allowing patients to return to work and daily activities sooner. In large PKP series, the rate of 20/40 or better vision has ranged from 47%–65% in Fuchs' dystrophy patients and from 20%–40% in patients with pseudo-phakic or aphakic bullous keratopathy.<sup>3–5,39</sup> Unfortunately, PKP can result in significant corneal distortion, so 10%–15% of PKP eyes generally require use of a hard contact lens for best vision, and in some cases, vision can be limited to counting fingers or worse.

DSEK is performed through a small incision and causes little to no corneal distortion. A mean corrected distance visual acuity (CDVA) of 20/40 is generally achieved within 3–6 months of DSEK, and over 90% of patients without ocular comorbidities achieve 20/40 or better vision.<sup>9,13</sup> A small percentage of patients who have undergone DSEK reach less than 20/40 vision because of irregularities resulting from the lamellar dissection or from folds that form in the donor tissue as it conforms to the back of the recipient cornea.<sup>40</sup> Thinner DSEK tissue provides better vision than thicker tissue.<sup>21</sup>

With DMEK, the visual recovery is impressive. In patients without ocular comorbidities, greater than 70% of those who have undergone DMEK achieve 20/25 or better vision within 3 months.<sup>35,41</sup> Overall the visual acuity achieved with DMEK is comparable with that in normal eyes, and DMEK achieves a more normal posterior corneal surface with fewer higher-order aberrations than DSEK or PKP.<sup>41</sup> Visual recovery is so rapid after DMEK that fellow eyes can be treated within 1–2 weeks of each other, with or without combined cataract extraction.<sup>42</sup>

### Refractive Changes

In contrast to PKP, EKP causes little to no change in corneal topography, resulting in far less change in spherical equivalent or cylinder. PKP induces +4.00–+5.00 diopters (D) of refractive cylinder on average and may exceed +8.00 D.<sup>3,5</sup> DSEK and DMEK cause no significant increase in mean refractive cylinder.<sup>9,13,35</sup> DSEK generally induces +0.50–+2.00 D of hyperopia,<sup>9,13</sup> whereas DMEK causes a smaller mean hyperopic shift of about +0.25–+0.50 D.<sup>35</sup>

### Graft Survival

It is not unusual for surgeons who are learning to perform EKP to initially have a higher rate of primary graft failure caused by surgical trauma. However, with experience, the primary graft failure rate should drop to the low levels seen with PKP.

In an initial consecutive DSEK series, the 5-year graft survival rate was similar to that reported for PKP in the large multicenter Cornea Donor Study (95% versus 93% for Fuchs' dystrophy and 76% versus 73% for pseudo-phakic or aphakic corneal edema).<sup>43,44</sup> PKP regrafts generally have a poor 5-year survival rate of 53% or less,<sup>6,39</sup> whereas the 4-year survival rate for DSEK under failed PKP was 74% in an initial consecutive series.<sup>28</sup>

Previous glaucoma surgery is a major risk factor for graft failure. Five-year DSEK graft survival was 95% in a series of eyes without previous glaucoma surgery versus 48% in eyes with one or more previous trabeculectomy or glaucoma tube shunt surgeries.<sup>45</sup>

## Complications

### Graft Detachment

Lack of complete adherence between the donor tissue and host cornea is the most frequent early complication with EKP. Reported rates have ranged from 0%–82%.<sup>9,13</sup> Detachment is addressed by reinjecting air into the eye. Keys to minimizing the risk of graft detachment are meticulous wound construction to preclude postoperative wound leaks, complete removal of fluid from the donor/host interface, achieving a firm air tamponade, and cautioning the patient not to rub the eye in the early postoperative period.

For partially detached DSEK grafts, observation is sufficient because they frequently will seal down spontaneously over time. With DMEK, partial detachments are more common and less likely to seal down spontaneously.

### Immunological Rejection

Immunological rejection is a leading cause of PKP failure. Allan et al. found that the incidence of an initial rejection episode within 2 years of

surgery was significantly lower with EKP than with PKP, and this difference was thought to be related to the frequently shorter duration of topical corticosteroid use after PKP to facilitate healing of the large incision.<sup>46</sup>

DMEK has an extremely low rate of initial rejection episodes. The 2-year probability of a rejection episode was less than 1% with DMEK, compared with 12% for DSEK and 18% for PKP, in a single-center study that utilized the same corticosteroid dosing regimen and rejection evaluation criteria for all three types of grafts and statistical methods that took length of follow-up into account.<sup>47</sup> These findings are consistent with reports from other centers that have had less than 1% cumulative rate of rejection with DMEK through 2 years compared with 3%–14% rates with DSEK.<sup>48–50</sup>

### Postkeratoplasty Intraocular Pressure Elevation

Intraocular pressure (IOP) elevation is fairly common after both EKP and PKP and primarily is associated with the prolonged use of topical corticosteroids to prevent graft rejection.<sup>51</sup> Previous history of glaucoma or ocular hypertension is a key risk factor. DMEK has such a low risk of graft rejection that it is safe to reduce the corticosteroid strength after about 1 month, and this dramatically reduces the risk of IOP elevation.<sup>52,53</sup>

EKP does not distort the corneal surface so it is easier to obtain accurate IOP measurements after EKP than it is after PKP. The addition of donor stromal tissue in DSEK does not alter IOP as measured with Goldmann applanation tonometry.<sup>54</sup>

### Infrequent Complications

Since EKP is performed with a small incision and the graft is held in place with an air bubble rather than by sutures, it avoids the suture-related complications seen after PKP, such as infiltrates/abscess, astigmatism, and suture erosions.<sup>9,13</sup> Moreover, being a closed-eye procedure, EKP provides greater tectonic stability and avoids the risk of suprachoroidal hemorrhage that can result in the loss of the eye with an open-sky procedure, such as PKP. However, interface irregularities can occur with lamellar procedures, such as EKP. Interface contaminants, such as retained viscoelastic or retained host DM with guttae, can distort vision. Epithelial down-growth or in-growth is also a rare but potentially serious complication with EKP, but it can be avoided with proper technique.

## OUTLOOK

Endothelial keratoplasty techniques continue to evolve. More work is needed to further facilitate EKP techniques, minimize endothelial cell loss, and more accurately predict the final refractive outcome following resolution of edema. Randomized prospective studies are needed to compare different techniques and determine the best methods.

Donor tissue remains scarce in developing nations. Ex vivo generation of donor corneal endothelium could allow more patients to benefit from

EKP despite a chronic worldwide shortage of donor corneas.<sup>55</sup> Studies suggest that in patients with Fuchs' dystrophy, it may be possible to stimulate host endothelial regeneration if the peripheral endothelium is relatively healthy despite central endothelial dysfunction. Further work is needed to accomplish this quickly and reliably.<sup>56</sup>

In conclusion, current EKP techniques have significantly increased the benefits and reduced the risks of grafting for patients with endothelial dysfunction. Future developments of EKP are expected to continue this beneficial trend.

## Surgical Ocular Surface Reconstruction

4.30

Neda Nikpoor, Victor L. Perez

**Definition:** Limbal stem cell deficiency is a devastating condition that can occur as the end result of a diverse set of etiologies. There are multiple surgical options to treat this disorder that may lead to corneal blindness.

**Key Features**

- Tissue harvested from the limbal region contains both corneal epithelium stem cells and immunogenic cells.
- Surgical approach depends on degree of ocular pathology and whether ocular damage is unilateral or bilateral.
- Autologous tissue transplantation always should be assessed first, and if allogeneic tissue is used, long-term systemic immunosuppression is necessary for graft survival.

**Associated Features**

- Concurrent ocular pathologies need to be addressed as much as possible prior to undertaking ocular surface reconstruction to improve the success of the procedure.
- Restoring normal eyelid anatomy and achieving a wet ocular surface prior to surgery are essential for good outcomes.
- Amniotic membrane has been shown to have a variety of desirable effects on the ocular surface.
- Laboratory ex vivo tissue expansion plays an important role in rehabilitating the ocular surface.

**INTRODUCTION**

The maintenance of the ocular surface is the result of a delicate balance between cell death and regeneration by two rapidly renewing tissues, the corneal and conjunctival epithelia. This capacity is dependent on a reservoir of stem cells at the limbus, with the ability to provide young epithelial cells to replace the dying or damaged cells. Corneal stem cells are located mainly in the palisades of Vogt of the limbal cornea rim, with the highest concentration in the superior and inferior limbus.<sup>1</sup>

Damage to the corneal stem cells can occur as a result of a variety of insults, including mechanical, hereditary, chronic inflammatory, and chemical.<sup>2-4</sup> Stem cell deficiency is characterized by conjunctivalization of the cornea associated with persistent epithelial defects, fibrovascular pannus, and stromal scarring and can lead to a variety of ocular surface diseases, ranging from mild ocular discomfort to corneal blindness. (Fig. 4.30.1).

**HISTORICAL PERSPECTIVES**

The first modern limbal stem cell transplantation was reported by Kenyon and Tseng in 1989.<sup>5</sup> More recently, in 1997, Pellegrini et al. suggested the possibility of expanding stem cells ex vivo for later transplantation.<sup>6</sup> Since then, multiple groups have published reports utilizing different methods of ocular surface reconstruction for a variety of surface pathologies.<sup>4,5,7-10</sup> With the ever-growing number of procedures around the world, the Cornea Society issued a standardized nomenclature in 2011.<sup>11</sup>

**General Concepts**

Some of the main principles of ocular surface reconstruction are as follows:

- The environment and the extracellular matrix on the surface of the eye on which corneal stem cells are transplanted have a profound effect on

**Fig. 4.30.1** A total stem cell failure as a result of severe alkali burn.

the success of the procedure. A moist, well-lubricated environment and proper lid anatomy are crucial for increasing the survival rate of these transplants.

- Tissue harvested from the corneal-scleral area includes corneal stem cells, fibroblasts, and Langerhans' cells. The limbus is a highly vascular part of the ocular surface allowing the immune cells to have access to this area. Therefore, proper immune suppression is an essential aspect of ocular surface reconstruction when an immune-compatible source of tissue is not available and an allogeneic graft is used.
- Corneal and conjunctival stem cells may be harvested from either the patient's contralateral eye (autografting) or from a cadaveric or living-related donor (allografting). Tissue from any of these sources then can be directly transplanted or expanded ex vivo in a laboratory. The selection of certain stem cell markers, such as p63 expressed in ex vivo expanded cells, can significantly improve long-term graft survival.<sup>12</sup> More recently, nonocular stem cells have demonstrated usefulness as a source for tissue.<sup>13</sup>

**PREOPERATIVE CONSIDERATIONS**

Some of the important aspects of preoperative evaluation are listed in [Table 4.30.1](#). Preoperative evaluation can guide the surgeon to the most appropriate modality of treatment and is vital to the success of the ocular surface rehabilitation. Foremost to this preoperative planning is distinguishing between primary and secondary ocular surface failures. Primary failure is the result of the direct causal agent, which can be chemical injury, inflammatory conditions, or infections. In contrast, secondary failure derives from factors that result in a decompensated ocular surface; these include elevated intraocular pressure as well as eyelid and tear abnormalities. Before attempting surgical reconstruction, both primary and secondary causes of ocular surface failure must be addressed and corrected. If appropriate, lid repair, mucous membrane grafting, tarsorrhaphy, and PROSE (prosthetic replacement of the ocular surface ecosystem) lenses can be utilized. In addition, a systemic evaluation must be performed to ensure that the patient is a good candidate for systemic immune suppression, if needed.

In general, patients with ocular surface disorders can be divided into two main groups: (1) those with total stem cell deficiency and (2) those with partial stem cell deficiency. Each group can then be further divided

**TABLE 4.30.1** Preoperative Considerations for Ocular Surface Reconstructive Surgery

Examination Element	Clinical Finding or Significance
Establishment of the diagnosis	Loss of palisades of Vogt, persistent epithelial defects, corneal pannus, etc.
Determination of the etiology of ocular surface disease	Primary (aniridia, ectodermal dysplasia, etc.); secondary (chemical injury, OCP, Stevens–Johnson syndrome, etc.)
Extent and severity of the disease	Cornea only or conjunctival involvement
Extent of ocular inflammation	Conjunctival inflammation, intraocular inflammation, etc.
Status of the fellow eye	If normal, may be a source of tissue for autografting
Coexistent ocular pathology	Glaucoma, adnexal pathology (e.g., trichiasis, etc.)
Ocular surface lubrication	Assessment of tear film insufficiency, and dryness are vital to success and may require additional surgical considerations
General health of the patient	Renal, cardiac, hepatic status if systemic immunosuppression is required

OCP, ocular cicatricial pemphigoid.

based on unilateral or bilateral disease, which can each be subdivided into partial versus total limbal stem cell deficiency (LSCD).

## OPERATIVE PROCEDURES

### Unilateral Disease

The prototypical example is unilateral chemical injury. Many of the treatment modalities discussed above for relative stem cell deficiency may be applicable to eyes with total stem cell deficiency with some modifications. For example, application of amniotic membrane may be helpful in terms of decreasing ocular surface inflammation as an adjunct to more definitive treatments.

The main advantage in cases of unilateral stem cell deficiency is that the contralateral, unaffected eye can be a source of immunologically compatible conjunctival and corneal cells, which may allow for a safer reconstitution of the ocular surface.

### Partial Stem Cell Deficiency

Surgical treatments are more successful in this group of patients because there are some reserves of stem cells present. Causes include entities, such as mild chemical burn, pterygia, and chronic ocular inflammation.

If the patient is asymptomatic or minimally symptomatic with a clear central visual axis, some partial peripheral conjunctivalization of the cornea can be well tolerated for long periods.<sup>7,8</sup> In these cases, simple lubrication with preservative-free artificial tears, topical anti-inflammatory drops, and close follow-up may be sufficient. In the case of acute trauma, some partial LSCD may be transient and can be observed for resolution with medical management.

For symptomatic patients there are three main surgical procedures that can be efficacious either individually or in combination. These include mechanical debridement, application of amniotic membrane, and autologous limbal stem cell transplantation.

#### Mechanical Debridement

If the visual axis or a larger portion of the peripheral cornea is covered by conjunctival tissue, simple mechanical debridement of this tissue may allow the remaining corneal stem cells to repopulate the central cornea with normal or near-normal epithelium. The procedure can be done with topical anesthesia and consists of debriding abnormal epithelium with a crescent blade or Weck–Cel sponge followed by the application of a bandage contact lens. The goal of this procedure is to provide the patient with a fairly clear visual axis and not to make the entire corneal surface normal. Some investigators have reported success with as little as two clock hours of normal limbal cells.<sup>6,7</sup> In a variant known as sequential sector conjunctival epitheliectomy (SSCE),<sup>14</sup> conjunctival sheets are debrided every 24–48 hours until the patient has completely re-epithelized. Regardless of the number or extent of debridement, patients should be placed on postoperative topical antibiotics and artificial tears. This procedure can be done in combination with an amniotic membrane graft as described below.

**Fig. 4.30.2** An amniotic membrane application shortly after severe chemical burn.

**Fig. 4.30.3** The same patient as in Fig. 4.30.2, 2 years after the placement of amniotic membrane tissue.

#### Amniotic Membrane Grafting

The most important properties of amniotic membrane harvested from the innermost layer of the placenta include the anti-inflammatory effect through downregulation of fibroblasts and providing a substrate for proliferation of the corneal and conjunctival epithelial cells.<sup>15,16</sup> These properties are only useful when some reserve of stem cells is present because the amniotic membrane itself is not a source of stem cells.

Work by Tseng and others has shown that the application of amniotic membrane to eyes with partial stem cell deficiency can improve ocular surface health and, in some cases, even restore a near-normal corneal epithelium.<sup>17–21</sup> Examples include acute and chronic chemical injuries, acute Stevens–Johnson syndrome, and iatrogenic stem cell deficiency. In these cases, application of the amniotic membrane, with or without mechanical debridement, can result in decreased ocular inflammation and allow the remaining corneal stem cells to repopulate the ocular surface.<sup>22</sup>

Amniotic membrane is commercially available in several forms, including a preserved wet amniotic membrane, a dehydrated form, and a contact lens–mounted membrane.<sup>23,24</sup> The amniotic membrane is placed on the eye with the epithelial side up to cover the area of interest. The membrane then can be secured to the cornea or episclera with 10-0 nylon sutures or fibrin glue (Figs. 4.30.2 and 4.30.3).

#### Autologous Limbal Stem Cell Transplantation

When there is relative or sectoral stem cell deficiency and the condition is unilateral, the unaffected part of the eye or the contralateral eye can serve as a donor for stem cells. Stem cells can be harvested from either the contralateral eye or from normal areas of the affected eye and transplanted to the area of stem cell deficiency. The first option is preferred. The surgical technique used is identical to that for an autologous graft for total stem cell deficiency and is described below.

## Total Stem Cell Deficiency

In general, if there is isolated LSCD in one eye, the treatment is autologous stem cell transplantation, or simple limbal epithelial transplantation (SLET). If LSCD and a conjunctival defect exist, the treatment involves conjunctival autograft. Presence of symblepharon, conjunctival defect, and LSCD may require mucous membrane grafting as well, depending on the size of the defect and extent of symblepharon.

### Autologous Limbal Stem Cell Transplantation

The traditional surgical approach involves careful dissection of the conjunctival tissue from the limbal area of the affected eye.<sup>25–28</sup> A rim of keratolimbal tissue from the contralateral eye, including a conjunctival rim and anterior cornea, can be harvested. Several tissue grafts can be harvested from the fellow eye. The superior and the inferior 4–5 clock hours of limbus offer the highest concentration of corneal stem cells. This tissue then can be carefully transported to the prepared bed with the maintenance of correct orientation. The tissue can be sewn into place by using nonabsorbable sutures, taking care not to pass the sutures through the harvested stem cell area. However, now that fibrin glue is widely available, it can be used to attach this tissue, thus avoiding the inflammatory reaction associated with sutures.<sup>29</sup> A bandage contact lens is then applied to the eye.

More recently, Sangwan et al. described SLET, a novel technique.<sup>30,31</sup> In this procedure a 2 × 2 mm or 1 clock hour section of autologous limbal tissue was excised from the uninvolved eye. The harvested graft was then divided into eight segments. After the host cornea was scraped of any fibrovascular epithelium, and an amniotic membrane secured with fibrin glue and the segments were placed epithelial side up on the optimized ocular surface and secured with fibrin glue, a bandage contact lens was then fitted to protect the tissue.

Postoperatively, patients are treated with antibiotics, corticosteroids, and preservative-free artificial tears. The bandage contact lens can be removed when the ocular surface is stable. Long-term systemic immune suppression is not necessary in these patients.

Prior to undertaking the harvesting of limbal tissue for stem cell transplantation, it should be clearly established that the fellow eye is not affected, and that there is an ample reservoir of stem cells present. A risk of inducing relative stem cell deficiency to the donor eye does exist if too much tissue is harvested. Most clinicians avoid taking more than 4 clock hours of tissue from the donor eye. When concern exists about the health of the fellow eye, allografts may be considered (see below). This method is highly successful, with graft survival rates reported up to 100% over a 47-month period.<sup>32,33</sup>

Basu et al. recently reported long-term follow up of 125 cases and found that with this approach, patients had notable improvement in the clinical appearance of their ocular surface as well as an increase in their visual acuity during the 1.5-year follow-up. The clinical factors associated with failure were identified as acid injury, severe symblepharon, and SLET combined with keratoplasty. In addition, the chapter authors' group has observed poorer outcomes in SLET patients who had autoimmune cicatrizing conjunctivitis as the cause of their LSCD.<sup>34</sup> Another indication for SLET is LSCD after treatment of ocular surface neoplasia. It should be noted that in this scenario, it would be prudent to defer ocular surface reconstruction of the affected eye until it has been established that there is no recurrence of the neoplasia.

## Bilateral Disease

Entities that can result in total stem cell failure in both eyes include severe chemical injuries, Stevens–Johnson disease, ocular cicatricial pemphigoid (OCP), and aniridia. Of note, many known bilateral disorders can be highly asymmetrical. In cases where a patient's history would suggest a bilateral process in the setting of a clinically unilateral process, the patient should be treated as having a bilateral LSCD to avoid possible donor site complications. The conditions in this group are the most difficult to address because the surgical options to rehabilitate the ocular surface are hindered by the lack of an immunologically compatible source of stem cells. This necessitates the use of either living-related donor tissue or cells harvested from cadaver eyes and aggressive systemic and topical immunosuppression.

### Keratolimbal Allograft and Allogeneic SLET

Keratolimbal tissue can be harvested from either a living-related donor's healthy cornea or from the whole globe or from corneal tissue of a cadaveric donor. The harvested allograft can then be transplanted directly onto

the injured eye. Neither living-related donors nor cadavers are perfect sources for grafts, and thus both advantages and disadvantages must be weighed.

Living-related donor transplants are advantageous in that harvested cells are typically more immunologically compatible than from a random source, especially if human lymphocyte antigen (HLA) matching is performed. Reinhard et al. demonstrated that this allows for longer survival time of the transplanted cells.<sup>35</sup> Specifically, they showed that over 5 years the grafts with only 0–1 HLA mismatches had a 65% success rate compared with 14% of unmatched tissue. Living-related donor tissue also has the benefit of stem cells that are fresh. One recent modification is the use of allogeneic SLET, which is surgically identical to SLET described above except that the donor eye is a living-related donor or cadaver rather than the patient's fellow eye. The disadvantage of all allogeneic limbal stem cell techniques is that even with HLA matching, postoperative systemic immunosuppression is required. Furthermore, the amount of tissue that can be harvested from the donor eye is limited, and there is a risk of inducing an ocular surface disorder in the healthy eye of a donor.

For keratolimbal allograft (KLAL), the tissue can be harvested under peribulbar anesthesia, similar to what has been described above for conjunctival limbal autograft. A total of 4 clock hours of tissue may be harvested, equally divided from the upper and lower limbus. This donor tissue then is placed onto the recipient eye after peritomy and superficial keratectomy have been performed to prepare the limbus. The donor tissue is secured to the cornea anteriorly and posteriorly to the episclera using either fibrin glue or 10-0 nylon sutures. Amniotic membrane may be transplanted at the same time, as needed.

In contrast, using cadaveric donor tissue allows the surgeon to harvest greater quantities of tissue than can be removed from living eyes. This theoretically improves the success of the ocular surface reconstruction, especially in eyes with severe stem cell deficiency. However, cadaveric tissue must be screened for communicable diseases. The time necessary for these tests along with tissue damage that occurs during standard tissue processing can result in stem cells of lower quality. The Minnesota Lions Eye Bank suggested certain criteria for tissue harvested for KLAL. These criteria include obtaining tissue from the youngest donor possible (including pediatric sources), taking care to avoid damage to limbal stem cells, including a 3–4 mm skirt of conjunctiva and a large corneoscleral rim, as well as obtaining both donor eyes to ensure adequate tissue.<sup>36,37</sup>

Some investigators advocate the use of more than one donor eye to allow complete coverage of the limbus.<sup>28</sup> Penetrating keratoplasty (PKP) or anterior lamellar keratoplasty (ALK) can be performed at the same time, or at a later setting when the ocular surface is more stable.<sup>26,28</sup> In 2010, Choi et al. reported a modified technique for both graft harvesting and host bed preparation by using a femtosecond laser, which showed good short-term results.<sup>38</sup>

Postoperatively, patients are treated with topical antibiotics, corticosteroids, and systemic immunosuppression. Because of the relative abundance of Langerhans' cells and HLA-DR antigens in the limbus, a high rate of immunological reaction can be expected, which may lead to recurrence of stem cell failure, necessitating aggressive and long-term immunosuppression. Although experts agree that postoperative long-term immunosuppressive therapy is necessary for the success of nonautologous grafts, the exact regimen and timeframe for treatment are highly variable. One commonly used method for postoperative immunosuppression is the Cincinnati protocol. This technique employs 1 year of corticosteroid coverage along with systemic tacrolimus, sirolimus, and mycophenolate.<sup>39</sup> It is not yet clear to what extent and for how long patients require immunosuppression after living-related and cadaveric allogeneic SLET.

The reported outcomes of KLAL vary, depending on the underlying disease entities and the duration of follow-up. A recent study reported successful improvement in ocular surface in up to 89% of living-related donors over a 32-month follow-up.<sup>17,32,40–42</sup> In contrast, the same study reported only a 33% success rate for cadaveric donor grafts over the same period. However, the long-term follow-up has shown a trend toward progressive decline of stem cell population and destabilization of the ocular surface despite systemic immunosuppression.<sup>43,44</sup>

### Ex Vivo Expanded Limbal Stem Cells and Nonocular Tissue

The majority of recent advancements in the area of stem cell transplants have focused on the harvesting and subsequent ex vivo expansion of limbal cells. Expansion of stem cells by culturing them in vitro theoretically provides a large supply of stem cells that can be used for surface reconstruction. This allows the surgeon to not only selectively remove fibroblast and Langerhans' cells, which may affect the long-term survival of allografted

cells, but also allows for minimal tissue to be excised from a donor source, decreased the potential risks associated with tissue harvesting.

In this approach, a minimal amount of limbal tissue (1–2 mm) is harvested either from an eye with relative stem cell deficiency, or the normal contralateral eye of a patient with unilateral total stem cell deficiency. In cases where severe and total bilateral stem cell deficiency exists, cells can be harvested from either a living-related donor or cadaver eyes. Studies have demonstrated the ability to use conjunctival tissue as well.<sup>45</sup> These cells then are amplified in culture media on a carrier, which will be utilized for transport and transplant of the cells onto the diseased eye. The exact method of ex vivo expansion varies widely, with success demonstrated under many conditions, including both explants and cell suspensions with or without 3T3 mouse fibroblasts and serum. However, regardless of the method for culturing the cells, obtaining a high percentage of p63-bright cells (>3% of all clonogenic cells) is of vital importance to the success of the graft.<sup>12</sup>

The amplified cells then may be mounted on a substrate. Current substrates include petrolatum gauze, denuded human amniotic membranes, fibrin, 3T3 cells, and bandage soft contact lenses. The recipient eye is then prepared in a similar manner to the method described for keratolimbal grafting. The cultured stem cells and their carrier are transferred onto the recipient bed, anchored to the limbus with 10-0 nylon sutures and to the surrounding conjunctiva with 8-0 Vicryl sutures. A bandage contact lens often is placed on the eye and kept in place until the ocular surface stabilizes.<sup>6,46–48</sup>

Although postoperative treatment for allogeneic tissue is similar to that for patients with keratolimbal grafts as described above, autologous tissue should be used when possible to avoid the need for immunosuppression.

Schwab et al. found improvement in the ocular surface of 60% of patients with autologous cells, and in all of the patients (total 4) with allogeneic cells combined with immunosuppression, with a mean follow-up period of 13 months.<sup>46</sup> Shimazaki et al., on the other hand, found only a 46.2% success rate in achieving a stable and healthy ocular surface in allografted patients.<sup>49</sup> Furthermore, in this report, the authors did not find a difference in success rate between this technique and cadaveric limbal transplantation combined with amniotic membrane. Baylis et al. recently reviewed 28 case reports and series regarding cultured limbal stem cells published over a 13-year period and compiled outcome data.<sup>50</sup> Despite wide variation in technique, they noted an overall success rate of 77% for autografts and 73% for allografts (76% overall). They also demonstrated that failures typically occurred in the first 2 years before stabilizing. In a 10-year study of 113 eyes reported in 2010, Rama et al.<sup>12</sup> showed a 76% success rate, with most failures occurring in the first year. They noted that, as mentioned earlier, grafts with more than 3% p63-bright cells had a 78% chance of success versus only 11% in those grafts with fewer than 3%.<sup>12</sup>

## SPECIAL CONSIDERATIONS IN OCULAR SURFACE RECONSTRUCTION

Other concurrent pathologies need to be addressed fully prior to undertaking ocular surface reconstruction to improve the success of the procedure. These may include the involvement of other subspecialties, such as oculoplastic surgery to address eyelid abnormalities and glaucoma to maximize pressure control.

### Ocular Surface Optimization

The ocular surface needs to be lubricated using treatments, such as preservative-free artificial tears, punctal occlusion, or PROSE lenses. A wet ocular surface is a requirement prior to proceeding with any surface reconstruction or limbal stem cell surgery. The use of autologous serum tears may be beneficial pre- and postoperatively. In fact, Gomes et al. established that preoperative dry eye was the single most important prognostic factor for graft survival. To this end, this team recently described the successful use of preoperative transplantation of labial mucous membranes and minor salivary gland transplantation to improve the ocular surface status.<sup>51</sup> Depending on the size of the defect and the extent of the symblepharon, conjunctival autograft (for unilateral LSCD with conjunctival defect) or mucous membrane grafting (for symblepharon or bilateral disease) may be necessary. One important point to consider in reconstructing the eyelid margin and palpebral conjunctiva is that the mucous membrane graft should be smooth and not so bulky as to cause trauma to the cornea. Furthermore, the ocular inflammation needs to be maximally and aggressively

treated with the use of topical and possibly systemic immune-modulating agents.

## Corneal Transplantation

Patients with stem cell failure often have corneal pathology, which may necessitate ALK or PKP. Performing keratoplasty in eyes with stem cell failure carries a very poor prognosis for graft survival because of chronic inflammation, vascularization of the ocular surface, and poor epithelial healing after surgery.

Corneal transplantation, however, may be more successful when the ocular surface has been reconstituted by using some of the approaches outlined above. The optimal timing for cornea transplantation is not well known. Some authors indicate that a stepwise approach, starting with stem cell transplantation followed by keratoplasty when the ocular surface is stable, may improve the graft survival.<sup>36,52</sup> The largest study of penetrating keratoplasty after cultivated limbal epithelial transplantation was reported by Sangwan et al., who reported a 93% success rate in terms of graft clarity, with a mean follow-up time of 8.3 months.<sup>52</sup> Currently, the literature supports a two-staged procedure for ocular surface rehabilitation. An article by Basu et al. compared an autologous cultivated limbal stem cell transplantation with either a simultaneous penetrating keratoplasty or a second procedure performed 6 weeks later.<sup>53</sup> Over a long-term follow-up, they noted an 80% graft survival for the staged procedure versus a 25% survival rate for the simultaneous technique (Figs. 4.30.4 and 4.30.5).

## CONCLUSIONS

In summary, the management of limbal stem cell deficiency requires careful preoperative case selection and control of comorbid factors, such

**Fig. 4.30.4** A cadaveric keratolimbal allograft with a subsequent penetrating keratoplasty.

**Fig. 4.30.5** The ocular surface of an eye in a patient with a total limbal stem cell deficiency following a chemical burn after a simultaneous cadaveric keratolimbal allograft, penetrating keratoplasty, and amniotic membrane tissue placement.

as eyelid anatomy, immune disease, and a wet ocular surface without exposure. Some techniques, such as minor salivary gland transplantation and mucous membrane grafts, may be useful in preparing the ocular surface for limbal stem cell transplants. In unilateral LSCD, the best results to date are with autologous stem cell transplantations, most recently with a trend toward SLET for most cases. A role still exists for ex vivo expansion of cells to avoid harm to the healthy donor eye. Bilateral cases can be treated with living-related donor or cadaver transplants and topical and systemic immunosuppression. Again, ex vivo expansion may play a role here. Finally, in refractory cases or for patients who are not candidates for the above-mentioned techniques, keratoprosthesis is an option.

# Management of Corneal Thinning, Melting, and Perforation

4.31

Nicoletta Fynn-Thompson, Michael H. Goldstein

**Definition:** Management of full-thickness or partial-thickness loss of corneal tissue.

## Key Features

- Concurrent, aggressive treatment of the underlying infectious or inflammatory condition.
- Multiple treatment options, depending on the clinical situation.
- The primary goal is to re-establish the tectonic integrity of the globe.

## Associated Features

- Typically a true ophthalmic emergency.
- Surgical management often warranted.

## INTRODUCTION

The integrity of the cornea can be compromised by both inflammatory and noninflammatory conditions, which may lead to stromal thinning, melting, and perforation. Progression may be slow over months to years, or may be rapid over hours to days. Rapid, proper recognition and management of these conditions is crucial to restore vision and to re-establish the integrity of the eye.

## CORNEAL THINNING FROM NONINFLAMMATORY DISORDERS

Noninflammatory corneal thinning disorders cause progressive ectasia caused by thinning of the stroma. The most common of these disorders include keratoconus, pellucid marginal degeneration, keratoglobus, and posterior keratoconus. Progressive corneal thinning (ectasia) is a rare but serious complication after laser refractive surgery. These conditions generally are slowly progressive. The primary goal, therefore, is to maintain functional vision (see Chapter 4.18 for more information).

## CORNEAL THINNING AND MELTING FROM INFLAMMATORY DISORDERS

Inflammatory corneal disorders can cause thinning with stromal melting. These conditions are often associated with pain, epithelial defects, corneal neovascularization, and other inflammatory changes. Progression is fast and emergent treatment is warranted upon diagnosis.

Noninfectious inflammatory causes include peripheral ulcerative keratitis (PUK), Mooren's ulcer, Terrien's marginal degeneration, and collagen vascular disorders. Infectious inflammatory causes include viral herpetic keratitis, bacterial keratitis, and fungal keratitis.

PUK suggests an autoimmune-mediated process and often is associated with rheumatoid arthritis. PUK (see Chapter 4.16) is seen with Wegener's granulomatosis, systemic lupus erythematosus, polyarteritis nodosa, ulcerative colitis, and relapsing polychondritis.

Medical treatment is directed both locally at the cornea and systemically to address the underlying systemic inflammatory process. The goals

of local (ocular) treatment are to (1) provide local supportive therapy to decrease corneal melting; and (2) promote re-epithelization of the corneal surface. These goals are accomplished using the following modalities: aggressive lubrication with preservative-free eyedrops and ointments, punctal occlusion, placement of a bandage contact lens, patching, oral doxycycline (or equivalent), and tarsorrhaphy. Topical collagenase inhibitors and corticosteroids are of some value, but may delay healing and cause perforation by initiating stromal melting. The goal of systemic therapy is to suppress the underlying systemic disorder with immunosuppressive or immunomodulatory therapy. If the underlying autoimmune disease is not treated, the corneal pathology will not improve.<sup>1-3</sup>

Inflammatory corneal disorders caused by infectious organisms (viral, bacterial, or fungal) also cause thinning and melting of the corneal stroma. Treating the pathogen aggressively with both topical and oral medications is most important to reduce further destruction of stromal tissue. Some advocate the use of concomitant corticosteroid drops once the infection is controlled, but this is controversial. If, despite aggressive therapy, stromal keratolysis progresses with development of descemetocoele, impending perforation, or frank perforation, the goal becomes maintaining the eye's integrity.

## SURGICAL TREATMENT OF CORNEAL PERFORATIONS

### Tissue Adhesives

Descemetocoeles or impending perforations can be stabilized or temporized by application of tissue adhesive and placement of a bandage contact lens with close follow-up. Studies have shown this procedure arrests the process of ulceration in noninfectious eyes. Application of tissue adhesive is much easier to perform in impending perforations than in frank perforations.<sup>4</sup> Frank corneal perforations, however, can be treated successfully with application of tissue adhesives. Although perforations measuring 1–2 mm are most successfully treated, those measuring up to 3 mm have been closed. Cyanoacrylate tissue adhesive traditionally has been used (Fig. 4.31.1).<sup>5</sup> Its

**Fig. 4.31.1** Corneal perforation sealed with cyanoacrylate glue. (Courtesy Michael H. Goldstein, MD.)

**Fig. 4.31.2** Technique for application of cyanoacrylate glue for treatment of larger corneal perforation. (A) Apply ointment to end of Q-tip. (B) Place small circular disc from cut drape onto Q-tip and adhere with ointment. (C) Place corneal glue onto disc and then place onto eye. (Courtesy Michael H. Goldstein, MD.)

use to seal corneal perforations was first reported in 1968.<sup>6</sup> Cyanoacrylate adhesive prevents re-epithelization into the zone of damaged stroma and prevents collagenase production, which leads to stromal melting.<sup>7</sup>

A common technique is described below, although several other excellent techniques exist. A thorough examination of the eye prior to application of the glue must be performed, with attention to the extent of perforation, possible lenticular damage, and possible uveal prolapse at the perforation site. Placing the patient in the supine position under an operating microscope is easier than examining the patient at the slit lamp. A topical anesthetic and lid speculum should be placed in the eye. Debridement of necrotic tissue from the ulcer crater is performed. This removed material is plated onto culture media to identify a possible infectious cause. The tissue adhesive adheres best to basement membrane so debridement of 1–2 mm of normal epithelium surrounding the ulcer allows for proper adhesion of the glue. A methylcellulose spear is used to dry the site. The tissue adhesive is then placed in microaliquots on the site of perforation with an applicator. The applicator can be a needle from a tuberculin syringe,<sup>8</sup> a 23-gauge Angiocath catheter (with the needle removed),<sup>9</sup> or a micropipette.<sup>10</sup> Alternatively, a polyethylene disc can be made and attached to a sterile wooden stick with ophthalmic ointment, and glue placed on the disc. Both are applied directly to the site of perforation (Fig. 4.31.2). The disc can then be removed or left in place.<sup>11,12</sup> The goal is to create a controlled method of placement of the smallest amount of glue to seal the perforation. The glue will solidify via polymerization over the next few minutes. A large, heaped mound over the crater is not necessary and can cause irritation and discomfort for the patient after the procedure.

The eye should be checked for evidence of leakage. If secure, then a bandage contact lens is applied, and the patient is checked at the slit lamp to confirm that the anterior chamber is forming and the glue is in place.

Application of tissue adhesive in frank corneal perforations is more challenging, as preparation of the site is more difficult secondary to the constant flow of aqueous from the perforation. Unless contraindicated, an air bubble can be placed into the anterior chamber to temporarily occlude the perforation by surface tension. Larger air bubbles risk pupillary block and increased intraocular pressure (IOP), so caution must be exercised.<sup>13</sup> In eyes with flat anterior chambers, to avoid incarceration of uveal tissue or the lens, viscoelastic material may be injected into the anterior chamber.<sup>14</sup>

Postoperatively, the patient may be placed on an aqueous suppressant, if medically tolerated. Patients with noninfectious perforations should receive a prophylactic broad-spectrum antibiotic four times daily. A protective shield should be kept in place at all times. Preservative-free artificial tears applied frequently will aid in lubrication with a bandage lens in place.

Patients also benefit from oral doxycycline because of its ability to inhibit collagenase. Depending on the cause, infected perforations are treated with frequent fortified antibacterial, antiviral, or antifungal therapy. Initially, patients should be examined daily, and any complaints of decreased vision, pain, tearing, or photophobia should be attended to immediately. If the bandage lens falls out, it must be replaced. If the glue becomes dislodged, reapplication is often necessary.

Corneal glue remains in place for weeks to months. It is recommended to leave it in place until it loosens and dislodges on its own, leaving behind a more healthy-appearing stromal tissue.

The reported potential complications for corneal tissue adhesive application include cataract formation,<sup>15</sup> corneal infiltrates, increased IOP,<sup>16</sup> giant papillary conjunctivitis,<sup>17</sup> retinal toxicity,<sup>18</sup> keratitis,<sup>19</sup> and iridocorneal and iridolenticular adhesions.<sup>20</sup>

Studies have shown that fibrin glue causes less neovascularization; however, a longer time is required for the adhesive plug to form. Application of fibrin glue has been shown to be successful with the additional placement of amniotic membrane grafts for structural support of a perforated cornea.<sup>21–25</sup>

## Penetrating Keratoplasty

If the corneal perforation is not amenable to treatment with corneal glue, then tectonic grafting is indicated (either a full-thickness or lamellar graft).<sup>8</sup> The smallest trephination capable of incorporating the site of perforation is chosen. Trephination of a soft eye is very difficult but is aided by the judicious use of viscoelastic materials. Alternatively, the temporary application of cyanoacrylate adhesive and sodium hyaluronate to create a normotensive eye has been described.<sup>26</sup> A customized hard contact lens applied with tissue adhesive to the corneal perforation has been reported to stabilize the eye and allow for trephination.<sup>27</sup> In some cases, handheld trephination may be needed. Care must be taken to avoid protrusion of ocular contents or damaging the iris or lens. The donor cornea should be secured with interrupted 10-0 nylon sutures.

Several case reports and case series have demonstrated the promising use of tectonic Descemet's stripping automated endothelial (DSAEK) in managing both impending and sterile corneal perforations.<sup>28,29</sup>

Postoperative care is challenging. A balance between reducing inflammation and the possibility of graft rejection, without significantly reducing the host's immunity, must be reached. Topical corticosteroids four times daily usually are required. Aggressive antibiotic, antiviral, or antifungal treatment is continued as indicated for infectious cases. For noninfectious cases, a broad-spectrum antibiotic is used four times daily.

**Fig. 4.31.3** Corneal perforation secondary to acute hydrops treated with patch graft. (Courtesy Michael H. Goldstein, MD.)

### Patch Graft

If the perforation is too large for a tissue adhesive, but too small for a full-sized penetrating keratoplasty (PKP) procedure, then a corneal patch graft can be helpful (Fig. 4.31.3). These procedures can temporarily stabilize a perforation or descemetocoele or may be a permanent treatment. It is ideal for peripheral pathology. Care should be taken when used for central pathology because it can interfere with visual outcome.

Gamma-irradiated sterile cornea now is available and very helpful in emergency situations. This tissue has a long shelf life, increasing the number of corneas suitable for transplantation. This tissue eliminates the risk of infection because of its preparation. It can be used only when viable endothelium is not necessary. Preliminary studies show it is useful in corneal patch graft surgery.<sup>30</sup>

### Miscellaneous Treatments

Multilayered amniotic membrane grafts alone may be successful in treating nontraumatic corneal perforations. More favorable outcomes are limited to perforations measuring less than 1.5 mm in diameter.<sup>13,31</sup> As

mentioned previously, amniotic membrane in conjunction with fibrin glue has been used to successfully close corneal perforations and restore globe integrity. Conjunctival flaps are useful for thinning due to ulcerations or descemetocoele formation but are contraindicated in corneal perforations. Conjunctival resection may be a useful adjuvant therapy in appropriate cases of corneal melting secondary to PUK.

### CONCLUSIONS

Corneal thinning, melting, and perforation can be caused by both inflammatory and noninflammatory conditions. Identification and treatment of these conditions is critical in the successful management of these patients. If impending or actual perforation occurs, immediate action must be taken to restore the integrity of the eye. This can be done with tissue adhesives, patch grafts, PKP, or amniotic membrane grafts.

# Basic Science of the Lens

Michael E. Boulton

## 5.1

IN THIS CHAPTER  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** A normally transparent intraocular structure whose function is to alter the pathway of light that has entered the eye to focus the image on the retina.

### Key Features

- Normally transparent at birth.
- Increasing opacity with age, infection, surgery, trauma, various metabolic states.
- Can alter shape and refractive power to allow for accommodation.

### Associated Features

- Asymmetric oblate spheroid shape.
- Avascular.
- Located posterior to the iris and anterior to the vitreous body.
- Spectral filter.
- Suspended by the zonules.

The lens is a transparent structure that has evolved to alter the pathway of the light entering the eye. In 2002, the World Health Organization estimated that lens pathology (cataract) was the most common cause of blindness worldwide, affecting more than 17 million people across the globe.<sup>1</sup> Cataract surgery is the most common surgical procedure performed in the developed world.<sup>2</sup>

The lens is an asymmetric oblate spheroid that is avascular and lacks nerves and connective tissue.<sup>3</sup> It is located posterior to the iris with its anterior surface in contact with the aqueous and the posterior surface with the vitreous. The lens is suspended by the zonular fibers that arise from the ciliary epithelium and insert 1–2  $\mu\text{m}$  into the outer part of the capsule.<sup>4</sup> Histologically the lens consists of three major components: capsule, epithelium, and lens substance (Fig. 5.1.1).

The lens capsule is an acellular envelope that is continuously synthesized by the lens epithelium anteriorly and fiber cells posteriorly. It is composed of a number of stacked lamellae, which contain major structural proteins and fibronectin.<sup>5</sup> The lens epithelium is a single layer of cuboidal cells approximately 10  $\mu\text{m}$  high and 15  $\mu\text{m}$  wide, located beneath the anterior capsule that extends to the equatorial lens bow. Their basal surface adheres to the capsule, whereas their anterior surface abuts the newly formed elongating lens fibers. The proliferative capacity of epithelial cells is greatest at the equator, and cells in the germinative zone are dividing constantly. Here, newly formed cells are forced into the transitional zone where they elongate and differentiate to form the fiber mass of the lens.<sup>3</sup> The bulk of the lens is composed of the nucleus and cortex, which comprise densely packed lens cytoplasm (“fiber cells”) with very little extracellular space.

The lens grows throughout life but at a slower rate with increasing age. The rate of increase in lens weight and equatorial diameter is greater than that of lens thickness.<sup>6</sup> Newly formed fibers are internalized as more are added at the transitional zone of the lens, and thus the newest fibers are in the outer cortex, and the oldest fibers are found in the center of the nucleus. Each growth shell, therefore, represents a layer of fibers that are younger than those in the shell immediately preceding it.<sup>7</sup>

**Fig. 5.1.1 Gross Anatomy of the Adult Human Lens.** Note the different regions are not drawn to scale.

The metabolic needs of the lens are met by the aqueous and the vitreous humor, with the majority of glucose and amino acids coming from the aqueous. The capsule is freely permeable to water, ions, other small molecules, and proteins with a molecular weight up to 70 kDa. In addition, epithelial cells and fibers possess a number of channels, pumps, and transporters that enable transcellular movement.

The lens acts as spectral filter and readily absorbs the energetic ultraviolet (UV) component of the electromagnetic spectrum that, if transmitted, has the potential to damage the retina. The overall transmission of visible light decreases with increasing age, a feature that arises largely from age-related changes and brunescence.<sup>8</sup> The refractive index of the lens increases from 1.386 in the peripheral cortex to 1.41 in the central nucleus. In addition, the curvature of the lens increases in a similar manner. Thus each successive layer of fibers has more refractive power and can bend light rays to a greater extent. When visible light passes through the lens, it is split into all the colors of the spectrum. The different wavelengths of these colors result in differences in refraction (chromatic aberration). As a consequence, yellow light (570–595 nm) normally is focused on the retina, blue (440–500 nm) anteriorly, and red (620–770 nm) posteriorly.<sup>9</sup> The lens is designed to minimize spherical aberration (defocus caused by greater refraction of light striking the peripheral lens compared to the center) in these ways:

- The refractive index increases from the periphery to the center of the lens.
- The curvature of both the anterior and the posterior capsule increases toward the poles.
- The curvature of the anterior capsule is greater than that of its posterior counterpart.

- Modulation of pupillary size prevents light from striking the periphery of the lens under nonmydriatic conditions.<sup>9,10</sup>

Accommodation is the process by which the lens changes its optical power by altering its shape and thus its focusing ability. At rest, the ciliary muscle is relaxed and the zonules pull on the lens keeping the capsule under tension and the lens flattened. Accommodation occurs when the ciliary muscle contracts, relaxing the zonules, thus increasing the curvature of the anterior surface and decreasing the radius of curvature from 10 mm to 6 mm. The increase in curvature of the anterior surface increases the refractive power. Accommodation is accompanied by a decrease in pupil size (miosis) and convergence of the two eyes.<sup>11</sup>

Adenosine triphosphate (ATP) is the principal source of energy of the lens, the majority of which comes from the anaerobic metabolism of glucose. Approximately 90%–95% of the glucose that enters the normal lens is phosphorylated to glucose-6-phosphate (G6P) in a reaction catalyzed by hexokinase. G6P is used either in the glycolytic pathway (80% of total glucose) or in the pentose phosphate pathway. The 5%–10% of glucose that is not converted to G6P either enters the sorbitol pathway or is converted into gluconic acid.<sup>12</sup>

The protein concentration within the lens is the highest in the body. The majority of ongoing synthesis generates crystallins and major intrinsic protein 26 (MIP26). The water-soluble crystallins constitute approximately 90% of the total protein content of the lens. The three groups of crystallins can be divided into the  $\alpha$ -crystallin family and the  $\beta/\gamma$ -crystallin superfamily.<sup>13</sup>

The continuous entry of optical radiation into the lens, especially UV (295–400 nm), makes the lens particularly susceptible to photochemical reactions leading to generation of reactive oxygen species (ROS). Protection against damage induced by ROS is achieved by a complex antioxidant system that relies heavily on superoxide dismutase, ascorbate, catalase, and glutathione peroxidase.<sup>14</sup>

Numerous morphological, biochemical, and biophysical changes occur to the lens with age.<sup>15</sup> Most notable are the age-related changes in color (more yellow), light transmission (decreased), consistency (increased hardness), loss of accommodative ability (manifested clinically as presbyopia), and protein aggregation. The resultant lens opacification, referred to as cataract, results in loss of light transmission.

While cataract surgery is safe and commonly performed, a major complication is development of a secondary cataract (posterior capsular opacification or Soemmerring's ring). Posterior capsular opacification (PCO) is the most common and can be further divided into fibrosis type and pearl type (Elschnig's pearls). Vision can be affected by blockage of the visual axis (both) or by progressive decentration of the intraocular lens (IOL) due to remnant lens epithelial cell proliferation and migration, epithelial-mesenchymal transition, collagen deposition, and generation of aberrant

lens fiber cells. Soemmerring's ring is often less visually significant, as the trapped and proliferating residual lens epithelial cells are located in the periphery, behind the iris.<sup>16</sup> While currently no definitive prevention exists, newer surgical techniques and IOLs may help to decrease the incidence of new cases. The current standard treatment involves the use of a neodymium:yttrium–aluminum–garnet (Nd:YAG) laser to perform a capsulectomy in the clinical setting.

In conclusion, the lens is a deceptively complex structure that allows for the transmission and refraction of light. An orderly structure, stable metabolic state, and intact antioxidant system are mandatory to maintain clarity. A full understanding of the basic science related to the lens allows for appreciation of the numerous pathologies that affect it and thus their medical and surgical treatment.

# Basic Science of the Lens

Michael E. Boulton

## 5.1

**Definition:** A normally transparent intraocular structure whose function is to alter the pathway of light that has entered the eye to focus the image on the retina.

### Key Features

- The lens comprises three parts: (1) the capsule, (2) the lens epithelium, and (3) the lens fibers.
- $\alpha$ -,  $\beta$ - and  $\gamma$ -crystallins constitute 90% of the total protein content of the lens.
- Lens function is dependent on the metabolism of glucose to produce energy, protein synthesis, and a complex antioxidant system.
- Lens transparency is dependent on the highly organized structure of the lens, the dense packing of crystallin, and the supply of appropriate nutrients.
- The lens can change its focusing power through a process called accommodation.
- The lens exhibits age-related changes in structure, light transmission, metabolic capacity, and enzyme activity.
- Secondary cataract occurs when residual lens cells after cataract extraction cause opacification of the visual axis.

### INTRODUCTION

The lens is a vital refractive element of the human eye. The World Health Organization estimates that lens pathology (cataract) is the most common cause of blindness worldwide, affecting over 17 million people.<sup>1</sup> Not surprisingly, cataract surgery is the most common procedure performed in the developed world.<sup>2</sup> An understanding of the basic science of the lens provides valuable insight into the various pathologies involving the lens and their treatment.

### ANATOMY OF THE LENS

The adult human lens is an asymmetric oblate spheroid that does not possess nerves, blood vessels, or connective tissue.<sup>3</sup> The lens is located behind the iris and pupil in the anterior compartment of the eye. The anterior surface is in contact with the aqueous; the posterior surface is in contact with the vitreous. The anterior pole of the lens and the front of the cornea are separated by approximately 3.5 mm.<sup>4</sup> The lens is held in place by the zonular fibers (suspensory ligaments), which run between the lens and the ciliary body. These fibers, which originate in the region of the ciliary epithelium, are fibrillin rich and converge in a circular zone on the lens. Both an anterior and a posterior sheet meet the capsule 1–2 mm from the equator and are embedded into the outer part of the capsule (1–2  $\mu$ m deep). It also is thought that a series of fibers meets the capsule at the equator.<sup>5,6</sup>

Histologically the lens consists of three major components—capsule, epithelium, and lens substance (Fig. 5.1.1).

### Capsule

The lens is ensheathed by an elastic envelope composed of epithelial cells and fibers that allows the passage of molecules both into and out of the lens. Capsule thickness varies by location (Fig. 5.1.2) and, except for the posterior capsule, increases with age.<sup>4–6</sup> The capsule is composed of a number of lamellae stacked on top of each other that are narrowest near the outside of the capsule and widest near the cell mass.<sup>7</sup> Major structural proteins and a small amount of fibronectin are found within the lamellae.<sup>8</sup>

This structure is continuously synthesized, anteriorly by the lens epithelium and posteriorly by the fiber cells.

### Epithelial Cells

The lens epithelium is a single layer of cuboidal cells approximately 10  $\mu$ m high and 15  $\mu$ m wide beneath the anterior capsule that extends to the equatorial lens bow. Their basal surface adheres to the capsule, whereas their anterior surface abuts the newly formed elongating lens cytoplasm (“fibers”). Lens epithelial cells have a large array of organelles and contain dense bodies and glycogen particles. Lateral attachment to adjacent cells occurs through both desmosomes and tight junctions.<sup>3,8–10</sup>

Lens epithelial cells contain three cytoskeletal elements: microfilaments (actin), intermediate filaments (vimentin), and microtubules (tubulin). These elements form a network that provides structural support, control of cell shape and volume, intracellular compartmentalization and movement of organelles, cell movement, distribution of mechanical stress, and mediation of chromosome movement during cell division.

**Fig. 5.1.1 Gross Anatomy of the Adult Human Lens.** Note the different regions are not drawn to scale.

**Fig. 5.1.2 Changes in Thickness of the Adult Lens Capsule With Location.**

Epithelial cell density is greatest in the central zone, where cells normally do not proliferate. These cells are the largest epithelial cells found in the lens. The proliferative capacity of epithelial cells is greatest at the equator (see Fig. 5.1.1). Cells here are dividing constantly, with newly formed cells being forced into the transitional zone where they elongate and differentiate to form the fiber mass of the lens.<sup>3,11</sup>

## Lens Substance

The lens substance, the bulk of the lens, is composed of densely packed lens cells with very little extracellular space. The adult lens substance consists of the nucleus and the cortex, which are often histologically indistinct. Although the size of these two regions is age dependent, a study of lenses with an average age of 61 years indicated that the nucleus accounted for approximately 84% of the diameter and thickness of the lens and the cortex for the remaining 16%.<sup>12</sup> The nucleus is subdivided into embryonic, fetal, infantile, and adult nuclei (see Fig. 5.1.1). The embryonic nucleus contains the original primary lens fiber cells that are formed in the lens vesicle. The rest of the nuclei are composed of secondary fibers, which are added concentrically at the different stages of growth by encircling the previously formed nucleus. The cortex, which is located peripherally, is composed of all the secondary fibers formed after sexual maturation.

Fibers are formed constantly throughout life by the elongation of lens epithelial cells at the equator. Initially, transitional columnar cells are formed, but once long enough, the anterior end moves forward beneath the anterior epithelial cell layer and the posterior end is pushed backward along the posterior capsule. The ends of this U-shaped fiber run toward the poles of both capsular surfaces.<sup>3–6</sup> Once fully matured, the fiber detaches from the anterior epithelium and the posterior capsule. Each new layer of secondary fibers formed at the periphery of the lens constitutes a new growth shell. Lens fibers are bound by the interlocking of the lateral plasma membranes of adjacent fibers. Both desmosomes and tight junctions are absent from mature lens fibers, although desmosomes are found between elongating fibers.<sup>3,8,9</sup>

## Sutures

Sutures are found at both the anterior and the posterior poles. They are formed by the overlap of ends of secondary fibers in each growth shell. No sutures are found between the primary fibers in the embryonic nucleus. Each growth shell of secondary fibers formed before birth has an anterior suture shaped as an “erect Y” and a posterior suture shaped as an inverted Y. The formation of sutures enables the shape of the lens to change from spherical to a flattened biconvex sphere.<sup>3,9,13</sup>

## Growth

The lens continuously grows throughout life but at a reduced rate with increased age.<sup>7</sup> The number of both epithelial cells and fibers increases by approximately 45%–50% during the first two decades of life (Fig. 5.1.3). After this, the increase in cell numbers is reduced, with the proportional increase in fibers being very small.<sup>3</sup> During an average lifespan, the surface area of the lens capsule increases from 80 mm<sup>2</sup> at birth to 180 mm<sup>2</sup> by the seventh decade.<sup>5,7</sup>

## Mass

The weight of the lens increases rapidly from 65 mg at birth to 125 mg by the end of the first year. It then increases at approximately 2.8 mg/year until the end of the first decade, reaching 150 mg. Thereafter, the rate slows to reach a weight of 260 mg by the age of 90 (see Fig. 5.1.3).<sup>14</sup> The average male lens weighs more than that of an age-matched female, with a mean difference of  $7.9 \pm 2.47$  mg.<sup>15</sup>

## Dimensions

The equatorial diameter of the human lens increases throughout life, slowing after the second decade. The diameter grows from approximately 5 mm at birth to 9–10 mm in a 20-year-old. The thickness of the lens also increases but at a much slower rate. The distance from the anterior to the posterior poles grows from 3.5–4 mm at birth, to 4.75–5 mm (unaccommodated).<sup>4,14</sup> The thickness of the nucleus decreases with age due to compaction, whereas cortical thickness increases as more fibers are added at the periphery. Because the increase in cortical thickness is greater than the decrease in size of the nucleus, the polar axis of the lens increases

### LENS WEIGHT AND CELL NUMBERS WITH AGE

**Fig. 5.1.3 Increase in Lens Weight and Cell Numbers With Age.** Note the correlation between these two parameters. (Lens weight data from Phelps Brown N, Bron AJ. Lens growth. In: Phelps Brown N, Bron AJ, Phelps Brown NA, editors. *Lens disorders. A clinical manual of cataract diagnosis*. Oxford: Butterworth-Heinemann; 1996. p. 17–31. Cell number data from Kuszak JR, Brown HG. Embryology and anatomy of the lens. In: Albert DM, Jakobiec FA, editors. *Principles and practices of ophthalmology. Basic sciences*. Philadelphia: WB Saunders; 1994. p. 82–96.)

with age.<sup>16</sup> The radius of curvature of the anterior surface decreases from 16 mm at the age of 10 years to 8 mm by the age of 80 years. There is very little change in the radius of curvature of the posterior surface, which remains at approximately 8 mm.

## PHYSIOLOGY OF THE LENS

### Permeability, Diffusion, and Transport

After involution of the hyaloid blood supply to the lens, its metabolic needs are met by the aqueous and vitreous humor. The capsule is freely permeable to water, ions, other small molecules, and proteins with a molecular weight of up to 70 kDa. Epithelial cells and fibers possess a number of channels, pumps, and transporters that enable transepithelial movement to and from the extracellular milieu.

### Transport of Ions

Fiber cells contain large concentrations of negatively charged crystallins. As a result, positively charged cations enter the lens cell to maintain electrical neutrality, and the osmolarity of the intracellular fluid becomes greater than that of the extracellular fluid. Fluid flow and swelling are minimized by the resting potential of the plasma membrane being set at a negative voltage through potassium (K<sup>+</sup>)-selective channels.

The Na<sup>+</sup> ions that leak into the cells are exchanged actively for K<sup>+</sup> ions, which diffuse through the lens down their concentration gradient and leave through ion channels in both the epithelial cells and surface fibers. There is a net movement of Na<sup>+</sup> ions from posterior to anterior and of K<sup>+</sup> ions from anterior to posterior.<sup>17</sup>

Although a pH gradient exists, which increases from the central nucleus to the periphery, the intracellular pH of the lens is approximately 7.0. Lens cells need to continually extrude intracellular protons, which accumulate due to inward movement of positive ions from the extracellular space and lactic acid from anaerobic glycolysis. The pH is regulated by mechanisms capable of increasing and decreasing intracellular acid levels. Molecules, especially proteins, also act as buffers.

### Amino Acid and Sugar Transport

The majority of amino acids and glucose enter the lens from the aqueous across its anterior surface. In addition, the lens can convert keto acids

**Fig. 5.1.4 Changes in Transmission (UV and Visible) of the Normal Aging Human Lens.** (From Boettner EA, Wolter JR. Transmission of the ocular media. *Invest Ophthalmol Vis Sci* 1962;1:776–83.)

into amino acids. The lens acts as a pump–leak system: Amino acids are “pumped” into the lens through the anterior capsule and passively “leak” out through the posterior capsule.

## BIOPHYSICS

### Light Transmission

The lens acts as a spectral filter absorbing long ultraviolet B (UV-B, 300–315 nm) and most of the UV-A (315–400 nm) wavelengths. While there is a transmission band centered around 320 nm of about 8% in children under 10 years, it is reduced to 0.1% by age 22. By age 60, no UV radiation transmits across the lens. The total transmittance of the young lens begins increasing rapidly at about 310 nm and reaches 90% at 450 nm, compared with the older lens, which begins transmitting at 400 nm but does not reach 90% total transmittance until 540 nm (Fig. 5.1.4). The overall transmission of visible light decreases with increasing age, a feature that arises largely from age-related changes and brunescence in the lens (see Fig. 5.1.4).<sup>18,19</sup>

### Transparency

The lens is opaque during the early stages of embryonic development. As development continues and the hyaloid vascular supply is lost, the lens becomes transparent. Transparency is due to the absence of chromophores able to absorb visible light and the presence of a uniform structure that scatters light minimally (less than 5% in the normal human lens). Light scatter is minimized in fiber cells once the fibers have elongated and their organelles have degenerated. Although the epithelial cells contain large organelles that scatter light, the combined refractive index of this layer and the capsule is no different from the refractive index of the aqueous, so light scatter is very small.

### Refractive Indices

The refractive index increases from 1.386 in the peripheral cortex to 1.41 in the central nucleus of the lens. Because both the curvature and refractive index of the lens increase from the periphery toward the center, each successive layer of fibers has more refractive power and therefore can bend light rays to a greater extent.<sup>20</sup> The anterior capsular surface of the lens has a greater refractive index than the posterior capsular surface (1.364–1.381 compared with 1.338–1.357). The increase in refractive index from the surface to the center results from changes in protein concentration; the higher the concentration, the greater the refractive power. This increase must occur as a result of both packing and hydration properties, because protein synthesis in the nucleus is minimal.<sup>18,21</sup>

### Chromatic Aberration

When visible light passes through the lens, it is split into all the colors of the spectrum. The different wavelengths of these colors result in different

**Fig. 5.1.5 Principal Aberrations of the Lens.**

rates of transmission through the lens and some deviation. As a consequence, yellow light (570–595 nm) is normally focused on the retina; light of shorter wavelengths, for example blue (440–500 nm), falls in front because of its slower transmission and increased refraction compared with yellow light. Light of longer wavelengths, for example red (620–770 nm), falls behind because of the faster transmission and less refraction (Fig. 5.1.5). Because the amount of dispersion between the red and the blue images is approximately 1.50–2.00 diopters (D), very little reduction occurs in the clarity of the image that is formed. As the lens accommodates, refraction increases as a result of the increasing power of the lens and, therefore, the amount of chromatic aberration also increases.<sup>20,22–24</sup>

### Spherical Aberration

The lens of the human eye is designed to minimize spherical aberration since: (1) refractive index increases from the periphery to the center of the lens; (2) curvature of both the anterior and the posterior capsule increases towards the poles; and (3) curvature of the anterior capsule is greater than that of its posterior counterpart.

As a result of these structural features, the focal points of the peripheral and central rays are similar, which ensures that reduction in the quality of the image is minimal (see Fig. 5.1.5). The pupil diameter also affects the amount of spherical aberration, because light rays do not pass through the periphery of the lens (unless the pupil is dilated). The optimal size of the pupil needed to minimize this imperfection is 2–2.5 mm.<sup>20,22–24</sup>

### Accommodation

The lens is able to change its shape and thus the focusing power of the eye. This process is known as accommodation, and it enables both distant and close objects to be brought into focus on the retina. At rest, the ciliary muscle is relaxed and the zonules pull on the lens keeping the capsule under tension and the lens flattened. Light rays from close objects are divergent and are focused behind the retina in this configuration. The lens

**Fig. 5.1.6 Change in Form of the Lens on Accommodation in a Person of Age 29 Years.** (A) Relaxed. (B) Accommodated. (Grid squares 0.4 mm.) Note the change in curvature of the anterior surface. (From Phelps Brown N, Bron AJ. Accommodation and presbyopia. In: Phelps Brown N, Bron AJ, Phelps Brown NA, editors. Lens disorders. A clinical manual of cataract diagnosis. Oxford: Butterworth-Heinemann; 1996. p. 48–52.)

accommodates these objects by contraction of the ciliary muscles, relaxing the zonules, thus increasing the curvature of the anterior surface and decreasing the radius of curvature from 10 mm to 6 mm. The increase in curvature of the anterior surface increases the refractive power, so that the light rays from close objects are refracted toward each other to a greater extent and, therefore, converge on the fovea. Because the front of the lens has moved forward, the depth of the anterior chamber decreases from 3.5 mm to 3.2–3.3 mm. Very little change occurs in the curvature of the posterior capsule, which remains at approximately 6 mm (Fig. 5.1.6). Accommodation is accompanied by a decrease in pupil size and convergence of the two eyes.

Accommodation can be divided into both physical and physiological processes. Physical accommodation, a measure of the change in shape of the lens, is measured in terms of the amplitude of accommodation using the unit diopter. It represents a measure of the extent to which objects close to the eye can be brought into focus. Physiological accommodation, a measure of the force of ciliary muscle contraction per diopter, is measured with the unit myodioter. The myodioter increases during the act of accommodation.<sup>25,26</sup>

## BIOCHEMISTRY

The lens requires energy to drive thermodynamically unfavorable reactions. Adenosine triphosphate (ATP) is the principal source of this energy, the majority of which comes from the anaerobic metabolism of glucose. Nicotinamide adenine dinucleotide phosphate (NADPH), which is produced principally via the pentose phosphate pathway, is used as a reducing agent in the biosynthesis of many essential cellular components, such as fatty acids and glutathione.

## Sugar Metabolism

Approximately 90%–95% of the glucose that enters the normal lens is phosphorylated into glucose-6-phosphate (G6P) in a reaction catalyzed by hexokinase. Although this enzyme exists as three different isoforms, only types I and II have been found in the lens. Type I has a greater affinity for glucose and is concentrated in the nucleus, where glucose levels are low. Type II, which accounts for 70% of the hexokinase, has a lower affinity for glucose and is found predominantly in the epithelium and cortex, where glucose levels are higher. G6P is used either in the glycolytic pathway (80% of total glucose) or in the pentose phosphate pathway (hexose monophosphate shunt; 10% of total glucose) (Fig. 5.1.7). Hexokinase is saturated by physiological concentrations of glucose found in the lens and limits the rate of both glycolysis and the pentose phosphate pathway. Glycolysis also is regulated by phosphofructokinase and pyruvate kinase.<sup>27,28</sup>

The lens lacks vascularity and thus exists in a hypoxic environment, which results in at least 70% of lens ATP being derived from anaerobic glycolysis. Approximately 3% of lens glucose passes into the more efficient tricarboxylic acid cycle (see Fig. 5.1.7), generating 25% of lens ATP. Glycolysis and the tricarboxylic acid cycle generate two energy-rich molecules; the reduced form of nicotinamide adenine dinucleotide (NADH) and the

reduced form of flavin adenine dinucleotide (FADH<sub>2</sub>). These donate their electrons to oxygen, which releases large amounts of free energy that is subsequently used to generate ATP. This cycle, which is restricted to the epithelial layer, also provides carbon skeleton intermediates for biosynthesis, such as amino acids and porphyrins.<sup>27,29</sup>

The bulk of the pyruvate produced by the glycolytic pathway is reduced to lactate by lactate dehydrogenase (see Fig. 5.1.7), which is concentrated in the cortex. The formation of lactate results in the reoxidation of NADH to NAD<sup>+</sup>. Glyceraldehyde-3-phosphate dehydrogenase regulates the activity of lactate dehydrogenase by controlling the rate of conversion of glyceraldehyde-3-phosphate into 1,3-diphosphoglycerate and, therefore, the availability of NADH.<sup>27–29</sup>

The 5%–10% of glucose that is not phosphorylated into G6P either enters the sorbitol pathway or is converted into gluconic acid (see Fig. 5.1.7). Glucose is converted into sorbitol by aldose reductase, an enzyme localized to the epithelial layer. Sorbitol is converted by polyol dehydrogenase into fructose, a less optimal substrate for glycolysis. Both sorbitol and fructose have the potential to increase osmotic pressure and may help to regulate the volume of the lens.<sup>27–29</sup>

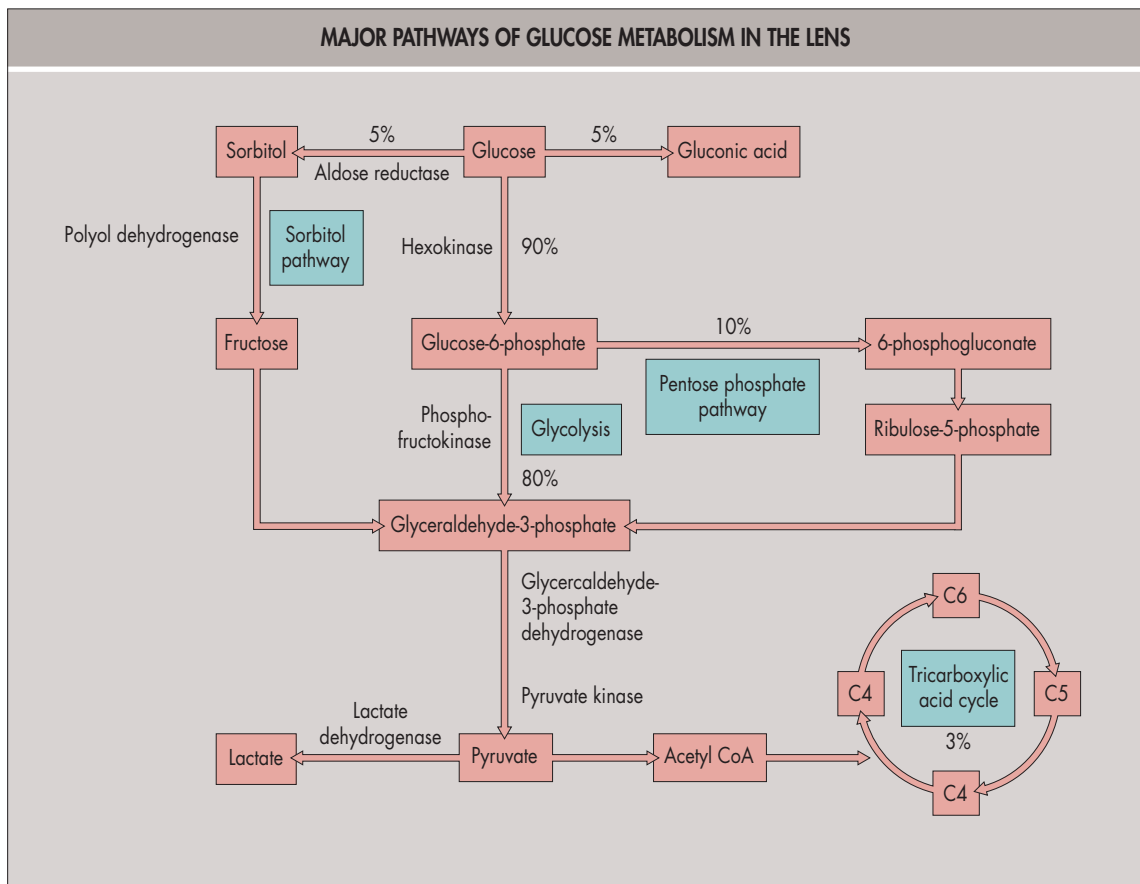

## Protein Metabolism

The protein concentration within the lens is the highest in the body. The majority of ongoing synthesis creates crystallins and major intrinsic protein 26 (MIP26). It is thought that this occurs in the epithelial cells and cortical fibers, which contain the organelles needed.<sup>30</sup>

Lens proteins remain stable for long periods because the majority of the degradative enzymes normally are inhibited. This is coordinated by marking those to be degraded with a small 8.5 kDa protein called *ubiquitin*. This system, which is ATP dependent, is most active in the epithelial layer. Lens proteins are broken down into peptides by endopeptidases and then into amino acids by exopeptidases. Neutral endopeptidase is activated by both calcium and magnesium and is optimal at pH 7.5 (the pH of the lens is approximately 7.0–7.2). The principal substrate of this enzyme is  $\alpha$ -crystallin. The calpains (I and II) are localized mainly in the epithelial cells and cortex and function to degrade crystallins and cytoskeletal proteins. They are cysteine endopeptidases, the activities of which are regulated by calcium. These enzymes are inhibited by calpastatin, a natural inhibitor found at higher concentrations than the calpains. The lens also contains a serine proteinase and a membrane-bound proteinase.<sup>28,29,31</sup> The main exopeptidase is leucine aminopeptidase, an enzyme optimal at pH 8.5–9.0, which catalyzes the removal of amino acids from the N-terminal of peptides. Aminopeptidase III has an optimal pH of 6.0 and as a result has a greater activity than leucine aminopeptidase in the normal lens.<sup>28,29,31</sup>

## Glutathione

Glutathione is found at high concentrations in the lens (3.5–5.5 mmol/g wet weight), especially in the epithelial layer. Glutathione has many important roles in the lens, including<sup>28,29,32</sup>:

**Fig. 5.1.7 Overview of the Major Pathways of Glucose Metabolism in the Lens.** Percentages represent the estimated amount of glucose used in the different pathways.

- Maintaining protein thiols in the reduced state, which helps to maintain lens transparency by preventing the formation of high molecular weight crystallin aggregates.
- Protection of thiol groups involved in cation transport and permeability; for example, oxidation of the -SH groups of the Na<sup>+</sup>,K<sup>+</sup>-ATPase pump, which results in an increased permeability to these ions.
- Protection against oxidative damage (see later in this chapter).
- Removal of xenobiotics; glutathione-S-transferase catalyzes the conjugation of glutathione to hydrophobic compounds with an electrophilic center.

### Amino Acid Transport

Glutathione has a half-life of 1–2 days and is recycled constantly by the  $\gamma$ -glutamyl cycle; its synthesis and degradation occur at approximately the same rate (Fig. 5.1.8). Glutathione is synthesized from L-glutamate, L-cysteine, and glycine in a two-step process that uses 11%–12% of lens ATP.<sup>28,29,32</sup> Reduced glutathione also can be taken into the lens from the aqueous. A reduced glutathione transporter that allows the uptake of glutathione by the lens epithelium has been characterized.<sup>33</sup> The breakdown of glutathione releases its amino acids, which are recycled.

### Antioxidant Mechanisms

The term reactive oxygen species (ROS) refers to highly reactive oxygen radicals that have the potential to damage lipids, proteins, carbohydrates, and nucleic acids. These include the superoxide anion, the hydroxyl free radical, hydroperoxyl radicals, lipid peroxyl radicals, singlet oxygen, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). ROS generally arise from cell metabolism or photochemical reactions. Photochemical damage occurs when light is absorbed by a photosensitizer that, upon photoexcitation, forms a transient excited triplet state that is long lived, allowing for interaction with other molecules producing free radicals or singlet oxygen. The continuous entry of optical radiation into the lens, in particular the absorption of shorter wavelengths (295–400 nm), makes lens tissue particularly susceptible to photochemical reactions. The major ultraviolet (UV) absorbers in the lens are free or bound aromatic amino acids (e.g., tryptophan), numerous pigments (e.g., 3-hydroxykynurenine), and fluorophores. Reactive oxygen species also can enter the lens from the surrounding milieu (e.g., H<sub>2</sub>O<sub>2</sub> is present at high levels in the aqueous humor, 30 mmol/L in humans).<sup>29,34</sup>

ROS have the capacity to damage the lens in many ways<sup>29,35</sup>:

- Peroxidizing membrane lipids results in the formation of aldehydes, which in turn can form cross-links between membrane lipids and proteins.
- Introducing damage into the bases of the DNA (e.g., base modifications) and reducing DNA repair efficiency.
- Polymerizing and crosslinking proteins result in crystallin aggregation and inactivation of many essential enzymes, including those with an antioxidant role (e.g., catalase and glutathione reductase).

Protection against damage induced by ROS is achieved in a number of ways. The superoxide anion undergoes dismutation by superoxide dismutase or by interaction with ascorbate (see below), which results in the formation of H<sub>2</sub>O<sub>2</sub>. This, along with the high levels of exogenous H<sub>2</sub>O<sub>2</sub>, is detoxified by the enzyme catalase or glutathione peroxidase or both (Fig. 5.1.9).<sup>36</sup> Catalase is present in epithelial cells at higher levels than in fibers. Glutathione peroxidase, however, is found in significant amounts in both epithelial cells and fibers. The glutathione system is thought to provide the most protection against H<sub>2</sub>O<sub>2</sub>, but it also protects against the lipid-free radical chain reaction by the neutralization of lipid peroxides.<sup>29,32,34,35</sup>

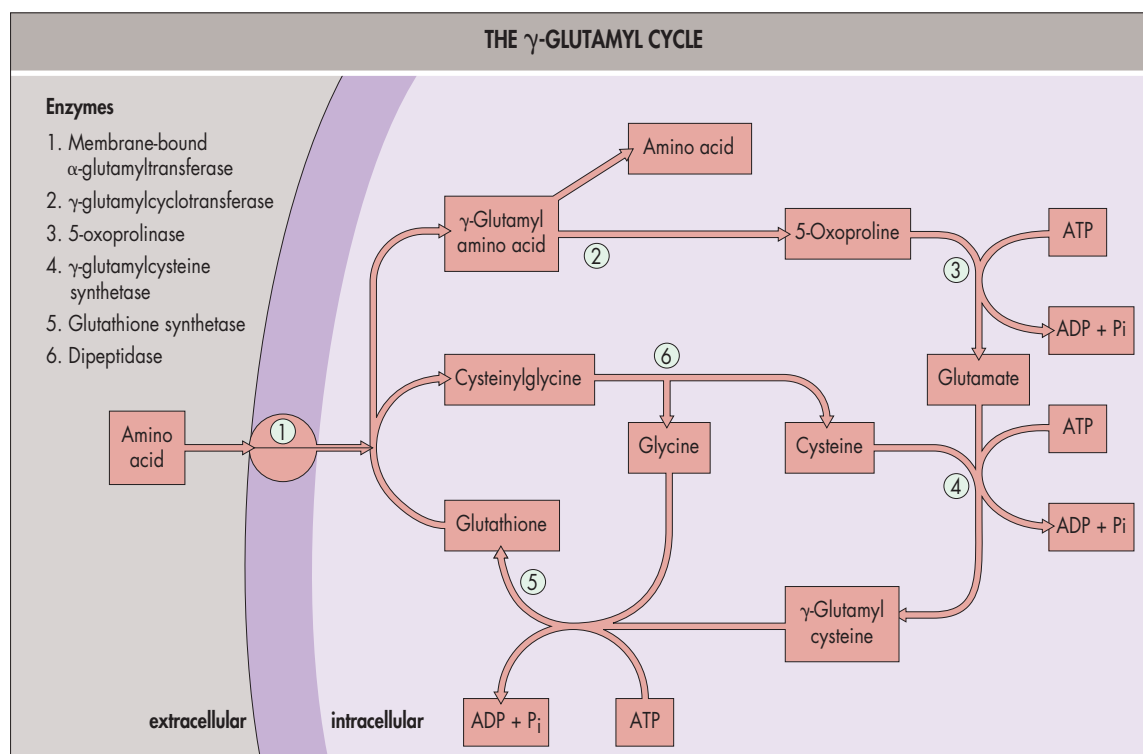

Ascorbic acid (vitamin C) plays a major role in the antioxidant system, although this may be species dependent, because the human lens is rich in ascorbate (1.9 mg/kg wet weight or 1.1 mmol/kg). Ascorbate is present at high levels in the outer layers of the lens but virtually absent from the nucleus. It reacts rapidly with superoxide anions, peroxide radicals, and hydroxyl radicals to give dehydroascorbate. It also scavenges singlet oxygen, reduces thiol radicals, and is important in the prevention of lipid peroxidation. The ascorbic acid and glutathione systems are coupled, as dehydroascorbate reacts with the reduced form of glutathione to generate ascorbate and GSSG (oxidized glutathione).<sup>31,34,37,38</sup>

This system, however, is not 100% efficient, and a low level of cumulative damage occurs throughout life.

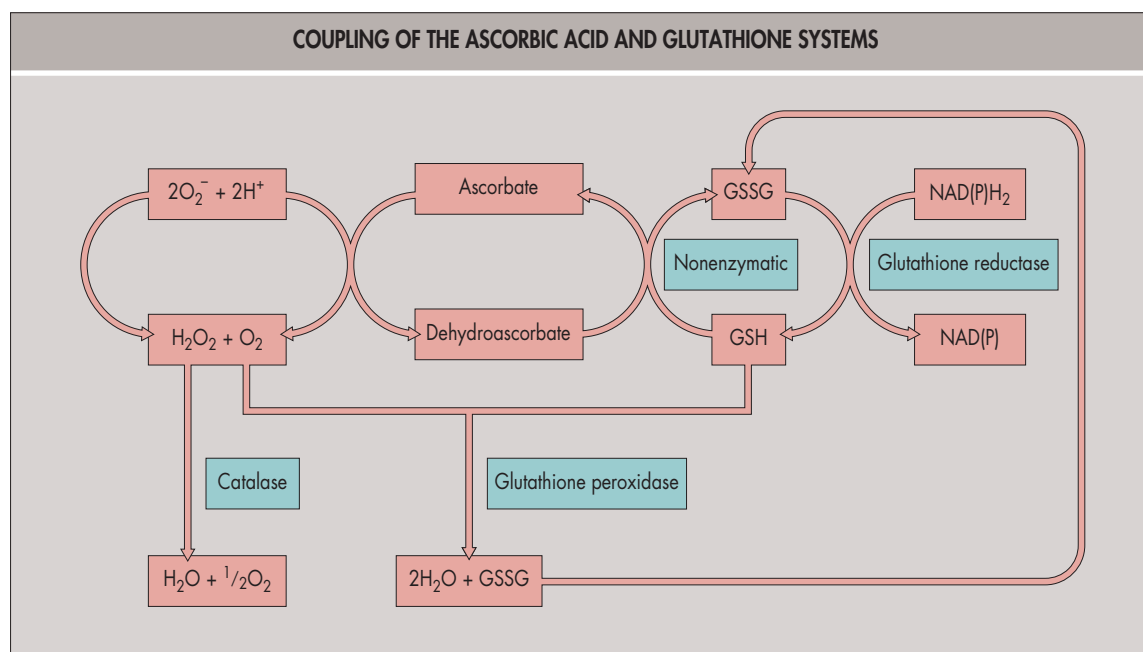

## LENS CRYSTALLINS

### Crystallin Structure

Up to 60% of the wet weight of the human lens is composed of proteins. These lens proteins can be subdivided into water-soluble (cytoplasmic proteins) and water-insoluble (cytoskeletal and plasma membrane) fractions.

**Fig. 5.1.8 The  $\gamma$ -Glutamyl Cycle.** (From Harding JJ, Crabbe MJC. The lens: development, proteins, metabolism and cataract. In: Davson H, editor. The eye. 3rd ed. London: Academic Press; 1984. p. 207–492.)

**Fig. 5.1.9 Coupling of the Ascorbic Acid and Glutathione Systems.**

The water-soluble crystallins constitute approximately 90% of the total protein content of the lens.<sup>39,40</sup>

The crystallins found in all vertebrate species can be divided into the  $\alpha$ -crystallin family and the  $\beta/\gamma$ -crystallin superfamily. The properties of these crystallins are summarized in Table 5.1.1. The  $\alpha$ -crystallins are the largest.

The  $\beta$ -crystallins are composed of light ( $\beta$ L) (c. 52 kDa) and heavy ( $\beta$ H) (150–210 kDa) fractions. The light fraction can be further subdivided into two fractions,  $\beta$ L1 and  $\beta$ L2.<sup>39–43</sup>

The smallest of the crystallins are the  $\gamma$ -crystallins. Six members of this family, known as  $\gamma$ A– $\gamma$ F, have a molecular weight of 20 kDa.

## Crystallin Gene Expression During Lens Growth

The  $\alpha$ -,  $\beta$ -, and  $\gamma$ -crystallins are synthesized in the human lens during gestation, and the absolute quantities of these crystallin families increases during development. The first crystallin to be synthesized is  $\alpha$ -crystallin, which is found in all lens cells. The  $\beta$ - and  $\gamma$ -crystallins are first detected in the elongated cells that emerge from the posterior capsule to fill the center of the lens vesicle.<sup>44</sup> Throughout life the same pattern of synthesis

is maintained, with the result that the  $\alpha$ -crystallins are found in both lens epithelial cells and fibers, whereas the  $\beta$ - and  $\gamma$ -crystallins are found only in the lens fibers.  $\alpha$ -Crystallin synthesis is far greater in the lens epithelium than in the fibers. The  $\alpha$ -crystallins are found in both dividing and nondividing lens cells, whereas the  $\beta$ - and  $\gamma$ -crystallins are found only in nondividing lens cells. Differentiation of a lens epithelial cell into a fiber, therefore, may be one of the factors that triggers a decrease in translation of the  $\alpha$ -crystallin gene and stimulates the synthesis of the  $\beta$ - and  $\gamma$ -crystallins.<sup>45</sup>

## Crystallin Function

The high concentration of crystallins and the gradient of refractive index are responsible for the refractive properties of the lens. The short-range order of these proteins ensures that the lens remains transparent.  $\alpha$ -Crystallins may be involved in the assembly and disassembly of the lens cytoskeleton. Similarities in structure between the small heat shock proteins (sHSPs) and  $\alpha\beta$ -crystallin suggest that this crystallin family may provide the lens with stress-resistant properties.<sup>40,41,46</sup>  $\alpha$ -Crystallins have chaperone-like functions that enable them to prevent the heat-denatured proteins from

TABLE 5.1.1 Properties of Different Crystallins

	$\alpha$	$\beta$	$\gamma$	$\gamma$ s
Subunits	$\alpha$ A, $\alpha$ A1, $\alpha$ B, $\alpha$ B1, up to nine minor subunits	Basic: $\beta$ B1, $\beta$ B2, $\beta$ B3 Acidic: $\beta$ A1, $\beta$ A2, $\beta$ A3, $\beta$ A4	$\gamma$ A– $\gamma$ F	$\gamma$ s
Subunit molecular weight	20 kDa	Basic: 26–32 kDa Acidic: 23–25 kDa	20 kDa	24 kDa

becoming insoluble and facilitate the renaturation of proteins that have been denatured chemically.<sup>47</sup> They also act as chaperones under conditions of oxidative stress and therefore may help to maintain lens transparency.<sup>48</sup>

Although the function of the  $\beta$ -crystallins is unknown, their structural similarities with the osmotic stress proteins suggest that they also may act as stress proteins in the lens.<sup>46</sup> The  $\gamma$ -crystallins (with the exception of  $\gamma$ s-crystallin) are found in the regions of low water content and high protein concentration, such as the lens nucleus. The presence of this family of crystallins correlates with the hardness of the lens. Concentrations are higher in those lenses that do not change shape during accommodation, as in fish, than in those that do, as in the human.<sup>40</sup>

## AGE CHANGES

### Morphology

Continued increases in both the mass and dimensions of the lens are greatest during the first two decades of life. This results from the proliferation of lens epithelial cells and their differentiation into lens fibers. The oldest epithelial cells are found in the middle of the central zone under the anterior pole. Because cells are added to the periphery of this zone throughout life, the age of the cells decreases from the pole toward the outer units of this region, so that the newest cells always are found near the pregerminative zone. Because newly formed fibers are internalized as more are added at the periphery of the lens, the oldest fibers are found in the center of the nucleus and the newest fibers in the outer cortex. Each growth shell, therefore, represents a layer of fibers that are younger than those in the shell immediately preceding it.<sup>49</sup>

As the lens ages, epithelial cells become flatter, flatten their nuclei, develop end-organ failure bodies and vacuoles, and exhibit a dramatic increase in the density of their surface projections and cytoskeletal components. The basal surface area of the cell increases; thus the number of cells needed to cover a region of the growing anterior capsule is less than that needed to cover a region of the same size in a younger lens. This, in combination with the decrease in proliferative capacity, means that epithelial cell density decreases as the lens ages.<sup>49,50</sup>

Lens fibers show partial degradation or a total loss of a number of plasma membrane and cytoskeletal proteins with age. The most significant degradation is that of MIP26. Early in life spectrin, vimentin, and actin are present in both the outer cortical fibers and the epithelial layer, but they are degraded as the fibers age and are further internalized. By 80 years of age, expression of these cytoskeletal proteins is restricted to the epithelial cells. The cholesterol-to-phospholipid ratio of fiber cell plasma membranes increases throughout life, and consequently membrane fluidity decreases and structural order increases. These changes, which are known to occur from the second decade, are greatest in the nucleus and are therefore partially responsible for the increase in nuclear sclerosis (hardening).<sup>51,52</sup>

**Fig. 5.1.10 Scanning Electron Micrograph of Equatorial Region of Cortical Fiber Plasma Membranes.** Note the circular shade with the fracture of fibers in the deep equatorial cortex (eq) (arrows) and folding fibers in the anterior deep cortex (ant) (arrowheads). (nu, lens nucleus). (From Vrensen GFJM. Aging of the human eye lens – a morphological point of view. *Comp Biochem Physiol A Physiol* 1995;111:519–32.)

Furthermore, the changes in structure of the plasma membrane and the degradation of cytoskeletal components may contribute to the increase in the number of furrowed membranes and microvilli found on the fiber surface.<sup>49</sup> From the fourth decade onward, ruptures are found in the equatorial region of cortical fiber plasma membranes (Fig. 5.1.10). Reparation of these ruptures often prevents the formation of opacities. Any opacities that do develop become surrounded by deviated membranes and are therefore isolated from the remainder of the lens.

The lens capsule thickens throughout life. It also increases in surface area as a result of the growth of the lens. Ultrastructural changes include the loss of laminations and an increase in the number of linear densities. Although the young lens capsule is known to contain collagen type IV and the aged capsule collagen types I, III, and IV, the presence of types I and III collagen in the young capsule has yet to be confirmed, but their synthesis may be age related.<sup>53</sup>

### Physiological Changes

Changes to the cellular junctions and alterations in cation permeability occur with age. The major gap junction protein MIP26 loses some of its amino acids to form new variants, which include polypeptides with molecular weights of 15, 20, and 22 kDa.<sup>51,52</sup> The membrane potential of an isolated, perfused human lens may be –50 mV at the age of 20 years, but only –20 mV at the age of 80 years. Potassium ( $K^+$ ) levels remain constant at approximately 150 mmol/L, but the sodium ( $Na^+$ ) content of the lens increases from 25 mmol/L at the age of 20 years to 40 mmol/L by the age of 70 years. Thus, the  $Na^+K^+$  permeability ratio increases approximately sixfold, which results in a proportionately greater increase in the sodium content of the lens.<sup>54</sup> The change in the ratio of these two ions correlates with the increase in optical density of the lens.<sup>55</sup> The change in ion permeability with increasing fiber age is thought to occur due to a decrease in membrane fluidity as a result of the age-related increase in the cholesterol-to-phospholipid ratio. The lens, therefore, becomes more dependent on the  $Na^+K^+$ -ATPase in the epithelial cells. The decrease in membrane potential also results from changes in the free  $Ca^{2+}$  levels, which increase from 10 mmol/L at the age of 20 years to approximately 15 mmol/L by the age of 60 years. It is thought that the  $Ca^{2+}$ -ATPase may be inhibited by the decrease in membrane fluidity, which decreases the rate at which  $Ca^{2+}$  is pumped out of the cell. It also is possible that the increase in  $Na^+$  and  $Ca^{2+}$  permeability may result from the increased activity of nonspecific cation channels.<sup>54</sup>

### Biophysical Changes

The absorption of both UV and visible light by the lens increases with age. Free and bound aromatic amino acids (tryptophan, tyrosine, and phenylalanine), fluorophores, yellow pigments, and some endogenous compounds

**Fig. 5.1.11 Main Species in the Human Lens That Absorb Light Transmitted by the Cornea.** (From Dillon J. The photophysics and photobiology of the eye. J Photochem Photobiol B 1991;10:23–40.)

(such as riboflavin) are responsible for the absorption properties of the lens.<sup>51</sup> Tryptophan is cleaved in the presence of sunlight and air to form N-formylkynurenine and a series of other metabolic products, including 3-hydroxykynurenineglucoside (3-HKG). Because more than 90% of the UV radiation that reaches the lens is UV-A (315–400 nm), and 3-HKG absorbs light between 295 and 445 nm whereas tryptophan only absorbs light between 295 and 340 nm, this glucoside has a relative absorbance that is greater than that of tryptophan in the young human lens (95% compared with 5%) (Fig. 5.1.11).

As the lens ages, it changes from colorless or pale yellow to darker yellow in adulthood, and brown or black in old age.<sup>55</sup> The autofluorescent properties of the lens also change with age. These changes in coloration, which are limited to the nucleus, are thought to result from the attachment of 3-HKG and its metabolic derivatives to proteins to produce yellow-pigmented proteins that also absorb light. As the concentration of these yellow pigments increases, they compete with 3-HKG and become the major absorbing species of the lens.<sup>56,57</sup> Because these yellow proteins are fluorescent species, the wavelength absorbed increases to approximately 500 nm (see Fig. 5.1.11). A blue fluorophore, which absorbs between 330 and 390 nm and fluoresces between 440 and 466 nm, increases as the lens ages. Oxygen-dependent photolysis of the blue fluorophore contributes to the formation of a green fluorophore, which is excited between 441 and 470 nm and emits between 512 and 528 nm.<sup>58</sup> The increased capacity of the lens to absorb visible light, in combination with the increased scattering properties of the lens (because of the aggregation of lens proteins and possibly the release of bound water), results in a decrease in transparency.<sup>50</sup> The increase in the total number of photons absorbed is accompanied by an age-related loss in antioxidant levels, increasing the amount of photo-oxidative stress.

Nonenzymatic glycation of proteins by the Maillard reaction results in the formation of advanced glycation end products, which also increase the yellowing of the lens. This reaction is initiated by the attachment of a sugar molecule (e.g., glucose) to an amino acid, normally valine or lysine. In young lenses, 1.3% of lysine residues of human crystallins are glycated, but by the age of 50 this increases to 2.7% and to approximately 4.2% in older lenses.<sup>51</sup> Yellow fluorescent photoproducts also are formed in the presence of ascorbic acid, which is present at high levels in the lens.<sup>59</sup>

## Accommodation Changes

The amplitude of accommodation decreases throughout life from 13.00–14.00 D at the age of 10 years to 6.00 D at 40 years and almost 0.00 D by the age of 60 years (Fig. 5.1.12). This manifests clinically as presbyopia. The change in accommodative power is attributable to a number of factors, including<sup>60–62</sup>:

- Young's modulus of capsular elasticity decreases from 700 N/cm<sup>2</sup> at birth to 150 N/cm<sup>2</sup> by the age of 80 years.

**Fig. 5.1.12 Presbyopic Changes in the Amplitude of Accommodation With Age.** The different colored symbols represent the data obtained from different publications. (From Fisher RF. Presbyopia and the changes with age in human crystalline lens. J Physiol 1973;223:765–79.)

- Stiffness of the lens substance increases, which renders the lens less deformable.
- Although the cortex increases in thickness throughout life, very little change occurs in the thickness of the nucleus. The effect of the rounding of the nucleus on the change in curvature of the anterior surface during accommodation, therefore, is reduced with age.
- The radius of curvature of the anterior capsule decreases, which renders the lens rounder. Contraction of the ciliary muscle, therefore, does not greatly alter the shape of the lens.
- The distance between the anterior surface of the lens and the cornea decreases.
- The internal apical region of the ciliary body moves forward and inward with age. The zonules, therefore, no longer put the lens under as much tension in the unaccommodated state.

The increases in curvature and thickness of the lens suggest that the refractive power should increase with age, resulting in myopia. This, however, does not happen because these changes are accompanied by small alterations to the gradient of refractive index. This gradient becomes flatter near the center of the lens and steeper near the surface and, therefore, the refractive power of the eye is lowered.<sup>63</sup>

## Biochemical Changes

The overall metabolic activity of the lens decreases with increasing age, partially due to decreasing enzyme activities in the cortex and nucleus. Many of the enzymes involved in the metabolism of glucose decrease with age, including glyceraldehyde-3-phosphate dehydrogenase, G6P dehydrogenase, aldolase, enolase, phosphoglycerate kinase, and phosphoglycerate mutase. Although overall metabolic activity decreases, the lens still maintains the capacity to synthesize proteins, fatty acids, and cholesterol at substantial rates. Decreased metabolic activity, therefore, does not serve as a significant limiting factor for the production of new lens fibers.<sup>51,52</sup>

A reduction in the activity or levels or both of many antioxidants occurs with increasing age. Because this decrease is greatest in the nucleus, fibers in this region of the lens are more susceptible to oxidative damage and lipid peroxidation. As a result, they rely on the overlying cortical fibers and epithelial layer to protect them. The activity of both catalase and superoxide dismutase decreases with age, as do levels of ascorbate and glutathione.<sup>50</sup> The reduced activity of both glutathione synthetase and  $\gamma$ -glutamylcysteine synthetase, accompanied by a decrease in the uptake of L-cysteine (an amino acid needed for glutathione synthesis), decreases the rate of synthesis of reduced glutathione (Fig. 5.1.13).<sup>64</sup> This is partly due to reduced activity of glutathione reductase, which converts oxidized glutathione into reduced glutathione. Glutathione peroxidase (which is involved in the breakdown of lipid peroxides and hydrogen peroxide) levels increase from birth until approximately 15 years of age and then slowly decrease

**Fig. 5.1.13 Effect of Age on the Capacity to Synthesize Reduced Glutathione.** (From Rathbun WB, Murray DL. Age-related cysteine uptake as rate-limiting in glutathione synthesis and glutathione half-life in the cultured human lens. *Exp Eye Res* 1991;53:205–12.)

**TABLE 5.1.2 Levels of Degraded Polypeptides in Water-Soluble High-Molecular-Weight Proteins of Human Lenses**

Donor's Age (years)	HMW Protein/Lens (mg)	HMW Protein-Associated Degraded Polypeptides/Lens (mg)	HMW Protein as Degraded Polypeptides (%)
16–19	0.16	0.009	5.6
38–39	0.93	0.17	18.2
49–51	2.17	0.255	11.75

throughout adulthood.<sup>51,52</sup> This decreased antioxidant activity coupled with increased photon absorption with increasing age promotes photo-oxidative damage in the lens.

## Crystallins

With increasing age an increase in both the complexity and the number of crystallin fractions occurs, which includes accumulation of high-molecular-weight (HMW) aggregates, partial degradation of crystallin polypeptides, increased crystallin insolubility, photooxidation of tryptophan, the production of photosensitizers, loss of sulfhydryl groups, and nonenzymatic glycation. These changes can alter the short-range spatial order of the crystallins and thus decrease transparency.<sup>50–52,56</sup>

Levels of soluble HMW aggregates (greater than  $15 \times 10^3$  kDa) increase from approximately 0.16 mg in the lenses of donors between the ages of 16 and 19 years to 2.3 mg by the age of 60 years (Table 5.1.2).<sup>65</sup> This increase occurs as the result of many factors, including reduced proteolytic enzyme activity. Most of these aggregates are localized to the lens nucleus and are, in the majority of the young, principally composed of  $\alpha$ -crystallin.<sup>50</sup> As the lens ages, these aggregates increase in complexity and become composed of a mixture of crystallins. The major subunits thought to be involved are  $\alpha$ A-,  $\alpha$ B-, and  $\gamma$ S-crystallins. Many of these polypeptides undergo posttranslational modifications, such as the formation of an intramolecular disulfide bond within  $\alpha$ A-crystallin, glycation of lysine residues, cross-linking, deamidation of  $\alpha$ A- and  $\gamma$ S-crystallins, and loss of the C-terminal end of  $\alpha$ A-crystallin. Such modifications to  $\alpha$ -crystallin result in a decrease in the capacity of this crystallin to act as a chaperone protein.<sup>50,66</sup> Below the age of 20 years, approximately 6% of the HMW protein is composed of degraded polypeptides, but by the age of 60 years this increases to 27% (see Table 5.1.2).<sup>65</sup>

**Fig. 5.1.14 Fibrosis of the Posterior Capsule.** This opacification developed in a 5-year-old child 20 days after extraction of a traumatic cataract (perforation with a knife). No intraocular lens was implanted. (From Rohrbach JM, Knorr M, Weidle EG, et al. *Nachstar: klinik, therapie, morphologic, and prophylaxe. Akt Augenheilkd* 1995;20:16–23.)

It is thought that many of the HMW aggregates act as precursors for the accumulation of insoluble proteins. Below the age of 50 years, approximately 4% of lens proteins are insoluble, but by the age of 80 years, this increases to 40%–50%.<sup>67</sup> The increase in insolubility is approximately the same in the cortex and nucleus before age 30 years, but with increasing age, insolubility increases to a greater extent in the lens nucleus. Up to 80% of the nuclear proteins of an aged lens may be insoluble, and most of the nuclear  $\alpha$ -crystallin is insoluble by the age of 45 years.<sup>51,52</sup> This contributes to the loss of lens transparency and the development of senile cataract.

Tryptophan residues in the crystallins are photooxidized to produce photosensitizers. This results in a decrease in tryptophan fluorescence and an increase in nontryptophan fluorescence throughout life. The oxidation of sulfhydryl groups results in the formation of disulfides, which may be one of the factors responsible for the age-related decrease in solubility of lens proteins. Because the  $\gamma$ -crystallins have sulfhydryl groups that are more exposed, they are more susceptible to this oxidation than are the  $\alpha$ - and  $\beta$ -crystallins.<sup>52</sup> Increases in the glycation of crystallins in the presence of glucose or ascorbic acid results in protein cross-linking and the resultant formation of HMW proteins. The  $\alpha$ - and  $\beta$ H-crystallins rapidly cross-link;  $\beta$ L-crystallins are slower, and no  $\gamma$ -crystallin cross-linking occurs. One of the modifications that occurs most frequently to aging crystallins is deamidation of asparagine residues, which results in the formation of aspartic acid residues, thus altering the structure, destabilizing the protein, and increasing its susceptibility to proteolytic degradation.

## SECONDARY CATARACT

A major complication of extracapsular cataract extraction (ECCE) is secondary cataract (also known as after cataract). Posterior capsule opacification (PCO) is the most clinically significant type of secondary cataract and develops in up to 50% of patients between 2 months and 5 years after the initial surgery. The frequency of PCO is age related; almost all children develop PCO after ECCE, but in adults the incidence is much lower. This is thought to be because of the higher proliferative capacity of lens epithelial cells in the young compared with the old.<sup>68,69</sup>

After ECCE, the lens is composed of the remaining capsule and the residual epithelial cells and cortical fibers that were not removed at the time of surgery. The lens epithelial cells still possess the capacity to proliferate, differentiate, and undergo fibrous metaplasia. Migration of these cells toward the center of the posterior capsule, together with the synthesis of matrix components, results in light scatter that reduces visual acuity. In a minority of cases, PCO results from the deposition of fibrin and other cell types onto the posterior capsule either at the time of surgery or postoperatively.<sup>69</sup>

The two morphologically distinct types of PCO are fibrosis and Elschnig's pearls, which occur concurrently. In addition, ECCE procedures may result in the formation of a Soemmerring's ring (Figs. 5.1.14–5.1.16).<sup>69,70</sup>

**Fig. 5.1.15 Elschnig's Pearls.** This opacification developed within 3 years of an extracapsular cataract extraction with implantation of a posterior chamber intraocular lens. (From Rohrbach JM, Knorr M, Weidle EG, et al. *Nachstar: klinik, therapie, morphologic, and prophylaxe. Akt Augenheilkd* 1995;20:16–23.)

**Fig. 5.1.16 Soemmerring's Ring.** Taken from behind the lens of a human eye obtained postmortem. A three-piece, modified J, polypropylene loop posterior chamber intraocular lens is present. (From Apple DJ, Solomon KD, Tetz MR, et al. *Posterior capsule opacification. Surv Ophthalmol* 1992;37:73–116.)

## Fibrosis-Type Posterior Capsule Opacification

Residual lens epithelial cells that are still attached to the anterior capsule after ECCE are thought to be the predominant cells involved in the formation of fibrous membranes that can appear within 2–6 months of ECCE.<sup>69</sup>

Remnant epithelial cells left on the anterior capsule differentiate into spindle-shaped, fibroblast-like cells (myofibroblasts), which express  $\alpha$ -smooth muscle actin and become highly contractile. These fibroblastic cells proliferate and migrate onto the posterior capsule to form a cellular layer that secretes extracellular matrix components and a basal lamina-like material. Cellular contraction results in the formation of numerous fine folds and wrinkles in the posterior capsule. At this stage the capsule is only mildly opacified. No significant visual loss occurs until the cells migrate into the visual axis.<sup>68,71</sup> More advanced stages of PCO result from further proliferation and multilayering of cells on the posterior capsule and are associated with additional extracellular matrix production and the appearance of white fibrotic opacities (see Fig. 5.1.14). The majority of the

extracellular matrix produced in the fibrosis type of PCO is composed of types I and III fibrillar collagen, collagen type IV, and a number of associated proteoglycans (dermatan sulfate, heparin sulfate, and chondroitin sulfate).<sup>72</sup>

In cases in which the cut edge of the anterior capsule rests on the intraocular lens (IOL) optic, residual anterior capsular cells may proliferate and extend from this cut edge onto the surface of the IOL, which may result in the formation of a membranous outgrowth within 1 week postoperatively.<sup>73</sup> Detailed studies using polymethylmethacrylate IOLs have shown that cells do not appear to cover the central part of the optic, and migration onto this optic decreases as the cells in the region of the anterior capsule in contact with the optic undergo fibrous metaplasia and begin to opacify. The cells on the IOL completely disappear within 3 months. It is also possible that cells may migrate around onto the posterior surface of the IOL implant and therefore contribute to the formation of PCO.

Growth factors present in both the aqueous and the vitreous have been implicated in the development of fibrosis-type PCO. These include acidic and basic fibroblast growth factors, insulin-like growth factor-I, epidermal growth factor, platelet-derived growth factor, hepatocyte growth factor, and transforming growth factor- $\beta$ .

## Pearl-Type Posterior Capsule Opacification

The pearls formed in this type of PCO are identical in appearance to Wedl (bladder) cells involved in the formation of posterior subcapsular cataracts (see Fig. 5.1.16). Because Wedl cells are known to originate from equatorial lens epithelial cells, it is believed that residual cells in this region of the capsule are the predominant cells involved in the formation of pearls. Clinically, cases of pearl formation occur somewhat later than those of fibrosis (up to 5 years postoperatively).<sup>69</sup>

Pearls were first observed by Hirschberg<sup>74</sup> in 1901 and then by Elschnig<sup>75</sup> in 1911; they now are referred to as Elschnig's pearls. After ECCE, the fiber mass of the lens is no longer present, and as a result, no internal pressure exists. Newly formed lens fibers, therefore, are no longer forced in the anterior and posterior directions, which results in the formation of a mass of cells loosely connected and piled on top of each other. Each pearl represents the aberrant attempt of one epithelial cell to differentiate into a new lens fiber, possessing characteristics of both epithelial cells and fibers, and may be embedded in an extracellular matrix. Visual acuity is affected only if the pearls protrude into the center of the posterior capsule.<sup>76–78</sup>

## Soemmerring's Ring

Soemmerring first noticed PCO in humans in 1828.<sup>79</sup> After ECCE, the cut edge of the remaining anterior capsular flap may attach itself to the posterior capsule within approximately 4 weeks postoperatively through the production of fibrous tissue. Any residual cortical fibers and epithelial cells, therefore, are trapped within this sealed structure. The equatorial cells still retain the capacity to proliferate and differentiate into lens fibers. The increase in the volume of this lenticular material fills the space between the anterior and the posterior capsule (see Fig. 5.1.16). Proliferating epithelial cells remain attached to the anterior capsule but also are found to a lesser extent on the posterior capsule, where they form small isolated groups. In some cases the epithelial cells escape from the ring and migrate onto the anterior surface of the anterior capsule. Because the ring forms at the periphery of the lens, vision is not affected.<sup>76,80,81</sup>

## Prevention and Treatment of Posterior Capsule Opacification

Currently there is no reliable treatment to prevent PCO. Posterior capsulectomy is the treatment of choice when PCO does affect the visual field. A posterior capsulectomy removes the central part of the posterior capsule and thereby instantly improves vision. Removal is achieved using a neodymium:yttrium–aluminum–garnet (Nd:YAG) laser (Fig. 5.1.17). In some patients with posterior segment problems, proliferation of lens epithelial remnants has been observed within months of the capsulectomy. As a result, the size of the capsulectomy decreases, which may in turn reduce visual acuity. It has been postulated that this occurs because of “activation” of the cells, the release of growth factors from the vitreous, the direct stimulation of proliferation, or a combination of these factors.<sup>82</sup> Removal of the barrier between the posterior chamber and the vitreous cavity increases the risk of complications such as cystoid macular edema, retinal detachment, uveitis, and secondary glaucoma.<sup>69</sup>

**Fig. 5.1.17 Posterior Capsule Following a Nd:YAG laser posterior capsulectomy.** (From Rohrbach JM, Knorr M, Weidle EG, et al. *Nachstar: klinik, therapie, morphologic, and prophylaxe. Akt Augenheilkd* 1995;20:16–23.)

There have been numerous approaches to prevent PCO.<sup>83,84</sup> The implantation of a posterior chamber IOL into the capsular bag after ECCE is known to reduce the likelihood that a patient will develop PCO, because the IOL acts as a barrier to the migration of cells around and into the center of the posterior capsule. Posterior convex or biconvex optics sit in the capsular bag with their posterior surface firmly against the posterior capsule. Barrier-ridge optics have a rim on the posterior surface of the IOL to try to block migrating cells. Migration also has been shown to be dependent on the implant biomaterial. For example, trials have shown that the posterior capsules of patients who were given polyacrylic implants were significantly clearer 2 years after implantation than the posterior capsules of those given polymethylmethacrylate or silicone implants. Lens epithelial cells also have been shown to regress in eyes implanted with polyacrylic IOLs.<sup>84</sup>

[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Report on the evolution of intraocular lens designs.

### Key Features

- Description of anterior and posterior chamber intraocular lens designs, including lenses now obsolete, and their interaction with intraocular tissues.
- Recent advances in intraocular lens designs/materials leading to modern, currently available intraocular lenses.

## INTRODUCTION

Cataract is the most prevalent ophthalmic disease. Although a pharmacological preventive or therapeutic treatment for this potentially blinding disease is being actively sought, the solution still appears to be many years away. Therefore, surgical treatment for cataracts, which typically includes intraocular lens (IOL) implantation, remains the only viable alternative. The implantation of IOLs is now a highly successful operation, and the safety and efficacy of the procedure are well established.<sup>1</sup>

## LENS DESIGN AND FIXATION

In 1967 Binkhorst<sup>2</sup> proposed a detailed classification of the various means of fixation for each IOL type. In a 1985 update of this classification, Binkhorst<sup>3</sup> listed four IOL types according to fixation sites: anterior chamber angle-supported lenses, iris-supported lenses, capsule-supported lenses, and posterior chamber angle (ciliary sulcus)-supported lenses. By common agreement, most surgeons today differentiate lens types as iris-supported lenses, anterior chamber lenses, and posterior chamber lenses.

From the time of Ridley's first lens implantation to the present day, the evolution of IOLs can be arbitrarily divided into six generations.

### Generation I (Original Ridley Posterior Chamber Lens)

Ridley's first IOL operation was performed November 29, 1949, on a 49-year-old woman at St Thomas' Hospital in London.<sup>4</sup> His original IOL was a biconvex polymethyl methacrylate (PMMA) disc designed to be implanted after extracapsular cataract extraction (ECCE) (Fig. 5.2.1).

### Generation II (Early Anterior Chamber Lenses)

As a consequence of the relatively high incidence of dislocations with the Ridley lens, a new implantation site was considered, with fixation of the lens in the angle recess. The anterior chamber was chosen because less likelihood existed of dislocation within its narrow confines. In addition, anterior chamber lenses could be implanted after either an intracapsular cataract extraction (ICCE) or an ECCE.

Late endothelial atrophy, corneal decompensation, and pseudophakic bullous keratopathy were observed with the original Baron anterior chamber lens and also developed with many subsequent anterior chamber

**Fig. 5.2.1 Posterior View of an Eye (Obtained Postmortem) Showing the Implantation Site of a Ridley Lens.** To the time of death, almost 30 years after implantation, the patient's visual acuity remained 20/20 (6/6) in both eyes. Note the good centration and clarity of the all-polymethyl methacrylate optic in the central visual axis. The lens was implanted by Reese and Hammdi of Philadelphia.

lens designs. The entity now termed uveitis–glaucoma–hyphema (UGH) syndrome was described first when ocular tissue damage occurred that was clearly the result of poorly manufactured early anterior chamber lenses.<sup>5</sup>

### Generation III (Iris-Supported Lenses)

Binkhorst was an early advocate of iris-supported IOLs.<sup>3,4</sup> His first lens was a four-loop, iris-clip IOL (Fig. 5.2.2A) design. Although Binkhorst initially believed that IOL contact with the iris would not cause problems, he soon noted that iris chafing, pupillary abnormalities, and dislocation developed with the early iris-clip lens. Also, in an effort to circumvent dislocation, Binkhorst made the anterior loops of his four-loop lens longer, but this led to increased corneal decompensation from peripheral touch. His initial implantations were done after ICCE, but occasionally he implanted his four-loop lens following ECCE. His positive experience with this procedure prompted him to modify his iris-clip lens design for implantation following ECCE. Binkhorst's change from ICCE to ECCE and the introduction of his two-loop iridocapsular IOL (see Fig. 5.2.2B) in 1965 were important advances in both IOL design and mode of fixation.<sup>6</sup>

### Generation IV (Intermediate Anterior Chamber Lenses)

As iris-supported IOLs underwent major modifications from the early 1950s up to the beginning of the 1980s, several designs of anterior chamber IOLs were introduced. The problems of tissue chafing and difficulties in correct sizing associated with rigid IOLs were addressed by the development of anterior chamber lenses with more flexible loops or haptics. Unlike the ill-fated, nylon-looped lenses introduced by Dannheim in the early 1950s, the fixation elements of these anterior chamber IOLs were made from

<sup>†</sup>Deceased

**Fig. 5.2.2 Binkhorst Iris-Clip Lenses.** (A) A correctly positioned Binkhorst four-loop, iris-clip lens, well centered in an eye that had good visual acuity. Moderate pupillary distortion and sphincter erosion occur. Note the iris-fixation suture superior to the site of the large iridectomy. (B) Posterior view of an autopsy globe that contains a two-loop iridocapsular intraocular lens. Note the rod that helps to secure the lens to the iris through the iridectomy. An outer Soemmerring's ring is present, but the visual axis remains clear. The optic is well centered.

**Fig. 5.2.3 Modern One-Piece, All-Polymethyl Methacrylate, Kelman-Style Anterior Chamber Lenses of Four-Point and Three-Point Fixation Designs.** Note the excellent polishing and tissue-friendly Choyce-Kelman-style footplates. These represent modern, state-of-the-art lenses that should be distinguished clearly from the earlier, unsatisfactory, closed-loop anterior chamber lenses.

more stable polymers, usually PMMA and polypropylene. The best lenses were the various rigid<sup>7</sup> and flexible, open-loop, one-piece PMMA designs, such as the three- and four-point fixation Kelman IOLs.<sup>8</sup> Modifications of the latter have been in use since the late 1970s and are the styles most commonly implanted today (Fig. 5.2.3).

### Generation V (Improved Posterior Chamber Lenses)

The return to Ridley's original concept of IOL implantation in the posterior chamber occurred after 1975. Pearce<sup>9</sup> of England implanted the first uniplanar posterior chamber lens since Ridley. It was a rigid tripod design with the two inferior feet implanted in the capsular bag and the superior foot implanted in front of the anterior capsule and sutured to the iris. Shearing<sup>10</sup> of Las Vegas introduced a major lens design breakthrough in early 1977 with his posterior chamber lens. The design consisted of an optic with two flexible J-shaped loops. Simcoe of Tulsa introduced his C-looped posterior chamber lens shortly after Shearing's J-loop design appeared. The flexible open-loop designs (J-loop, modified J-loop, C-loop, or modified C-loop) still account for the largest number of IOL styles available today (Fig. 5.2.4).

One obvious major theoretical advantage that a posterior chamber IOL has over an anterior chamber IOL is its position behind the iris, away from the delicate structures of the anterior segment. The return to posterior chamber lenses coincided with the development of improved ECCE surgery. Shearing identified four major milestones that have marked the

evolution of ECCE surgery: microscopic surgical techniques; phaco; iridocapsular fixation; and flexible posterior chamber lenses.

### Generation VI (Modern Capsular Lenses – Rigid PMMA, Soft Foldable, and Modern Anterior Chamber)

By the end of the 1980s, surgical technique and IOL design and manufacture had advanced to a point at which the older techniques gave way to more modern ones that allowed consistent, secure, and permanent in-the-bag (capsular) fixation of the pseudophakos. A marriage between IOL design and improved surgical techniques has evolved into capsular surgery. The “capsular” IOLs are fabricated from both rigid and soft biomaterials.

The many changes in surgical techniques that occurred after 1980 and into the 1990s include the introduction of ophthalmic viscosurgical devices (OVDs), increased awareness of the advantages of in-the-bag fixation, the introduction of continuous curvilinear capsulorhexis (CCC), hydrodissection, and the increased use of phaco. Improved small-incision surgical techniques and IOL designs have resulted in a natural evolution toward foldable lenses. Most foldable lenses today are manufactured from silicone, hydrogel, or acrylic material (Fig. 5.2.5).<sup>11,12</sup>

### RECENT ADVANCES

Some general principles and tendencies with regard to the development of new IOLs in the past decade are<sup>11,12</sup>:

- Large fixation holes or foramina incorporated in the haptic components of one-piece plate designs commonly produce fibrous adhesions between the anterior and posterior capsules following ingrowth of fibrocellular tissue through the holes, enhancing the fixation and stability of these designs within the capsular bag.
- For three-piece foldable designs, the preferred haptic materials are rigid materials with good material memory, such as PMMA, polyimide (Elastimide), or polyvinylidene fluoride (PVDF), which enhance lens centration and stability and provide better resistance to postoperative contraction forces within the capsular bag.
- One of the most important features in foldable lenses that decreases the incidence of posterior capsular opacification (PCO) is the square, truncated optic edge, which has an enhanced barrier effect against cell migration/proliferation on the posterior capsule toward the visual axis.
- Manufacturers have invested heavily and with great success in looped single-piece designs (Fig. 5.2.5B), including designs with modifications at the level of the optic-haptic junctions to obtain a nonsmooth transition between these components. This was done because some studies demonstrated that smooth optic-haptic junctions may be sites for PCO initiation.
- New injector systems to be used with the new lens designs have been developed. Manufacturers have also invested in the development of injector systems where the IOLs come preloaded and in automated injection systems.
- Special features such as multifocality, extended depth of focus, toric corrections, pseudoaccommodation, asphericity, postoperative adjustment

**Fig. 5.2.4 View From Behind of an Autopsy Eye.** (A) A Sinskey-style, J-loop posterior chamber intraocular lens implanted within the lens capsular bag. The optic is well centered, the visual axis is clear, and there is only minimal regeneration of cortex in scattered areas. Moderate haziness or opacity occurs at the margins of the anterior capsulotomy, which does not encroach on the visual axis. (B) The placement of the loop of this modified C-style intraocular lens in the capsular bag.

of the IOL refractive power, image magnification (telescopic lenses), and protection of the retina against blue or violet light (through incorporation of appropriate chromophores to the IOL optic material) are widely available.<sup>13</sup>

- The renewed interest in phakic IOLs, which can potentially correct any refractive error, is also progressing rapidly.<sup>14</sup> A trend exists for the use of foldable materials for these phakic lenses, designed to be inserted through small incisions and fixated to the iris or in the posterior chamber. Most of the angle-supported anterior chamber phakic IOLs have been abandoned from the market due to issues with the corneal endothelium.<sup>15</sup>
- There is a renewed interest in the piggyback IOL procedure not only for correction of residual refractive errors but also because of the potential to implant a low-power multifocal lens to provide spectacle freedom to patients who already are pseudophakic, as well as other specialized lenses such as toric and aspherical IOLs. In these cases, the “supplementary” lens is fixated in the ciliary sulcus to avoid interlenticular opacification (ILO) formation, and it is specially designed to minimize interaction with intraocular structures and provide appropriate clearance with uveal tissues and the in-the-bag IOL.<sup>16</sup>

# Evolution of Intraocular Lens Implantation

## 5.2

Liliana Werner, Andrea M. Izak, Suresh K. Pandey, David J. Apple<sup>†</sup>

**Definition:** Report on the evolution of intraocular lens designs.

### Key features

- Description of anterior and posterior chamber intraocular lens designs, including lenses now obsolete, and their interaction with intraocular tissues.
- Recent advances in intraocular lens designs/materials, leading to modern, currently available intraocular lenses.

## INTRODUCTION

Cataract is the most prevalent ophthalmic disease. The number of persons who became blind as a result of cataract in 1998 was estimated to be about 17 million worldwide; this number was expected to double by early in the twenty-first century.<sup>1,2</sup> Although a pharmacological preventive or therapeutic treatment for this blinding disease is being actively sought, the solution still appears to be many years away. Therefore, surgical treatment for cataracts, which increasingly includes intraocular lens (IOL) implantation, remains the only viable alternative.

Treatment of cataracts has been practiced for centuries using various surgical and nonsurgical procedures. However, avoidance of complications and attainment of high-quality postoperative visual rehabilitation were difficult in the years before the introduction of modern IOLs. Because significant dioptric power resides in the crystalline lens, its removal results in marked visual disability.

Aphakic spectacle correction has been prescribed throughout history, but spectacles are less than satisfactory because of the visual distortions inherent in such high-power lenses.

It was not until the late 1940s that the optical advantages that an IOL could provide in visual rehabilitation were understood and acted on by Ridley.<sup>3-7</sup>

The implantation of IOLs is now a highly successful operation; the safety and efficacy of this procedure are well established. The number of IOL implants in the United States in 1998 was estimated to be 1.6 million. Implantation data from other countries are scant, but the total number of implantations per year worldwide is increasing rapidly. Studies are still needed to determine which surgical technique(s) and which IOL design(s) are safest, most practical, and most economical for high-volume use in the less advantaged areas of the world. For general discussions that review the evolution and provide clinicopathological overviews of IOLs, see Apple and coworkers<sup>7-10</sup> and Binkhorst.<sup>11</sup>

Posterior chamber IOLs were reintroduced in the mid-1970s and early 1980s, following a long period of disfavor after the Ridley lens was discontinued. Jaffe and other authors compared posterior chamber lenses with iris-supported lenses and were impressed by the superior results achieved with the former type of lens using an extracapsular cataract extraction technique. The use of posterior chamber IOLs is now clearly the treatment of choice.

## LENS DESIGN AND FIXATION

In 1967, Binkhorst<sup>11</sup> proposed a detailed classification of the various means of fixation for each IOL type. In a 1985 update of this classification, Binkhorst<sup>12</sup> listed four IOL types according to fixation sites:

- Anterior chamber angle-supported lenses.
- Iris-supported lenses.
- Capsule-supported lenses.
- Posterior chamber angle (ciliary sulcus)-supported lenses.

By common agreement, most surgeons today differentiate lens types as follows:

- Iris-supported lenses.
- Anterior chamber lenses.
- Posterior chamber lenses.

From the time of Ridley's first lens implantation to the present day, the evolution of IOLs can be arbitrarily divided into six generations (Table 5.2.1).

### Generation I (Original Ridley Posterior Chamber Lens)

A practical application of the concept of IOLs began with Ridley,<sup>3-7</sup> and credit for the introduction of lens implants clearly belongs to him.

Ridley's first IOL operation was performed on a 49-year-old woman at St Thomas' Hospital in London on November 29, 1949. His original IOL was a biconvex polymethyl methacrylate (PMMA) disc designed to be implanted after extracapsular cataract extraction (ECCE) (Fig. 5.2.1).

Ridley's procedure was initially met with great hostility by several skeptical and critical ophthalmologists. However, good results were attained in enough cases to warrant further implantation of the Ridley IOL, although dislocation of the lens ultimately proved troublesome. It is gratifying to note that Ridley, who died in 2001, lived long enough to experience the acknowledgment, respect, and honor he so fully deserved for this innovation.

### Generation II (Early Anterior Chamber Lenses)

As a consequence of the relatively high incidence of dislocations with the Ridley lens, a new implantation site was considered—the anterior chamber, with fixation of the lens in the angle recess. The anterior chamber was chosen because less likelihood existed of dislocation within its narrow confines. In addition, anterior chamber lenses could be implanted after either an intracapsular cataract extraction (ICCE) or an ECCE. Also, anterior chamber placement of the pseudophakos was considered a simpler technical procedure than placement of the lens behind the iris.

TABLE 5.2.1 The Evolution of Intraocular Lenses

Generation	Date	Description
I	1949–1954	Original Ridley posterior chamber lens
II	1952–1962	Early anterior chamber lenses
III	1953–1975	Iris-supported lenses
IV	1963–1990	Intermediate anterior chamber lenses
V	1975–1990	Improved posterior chamber lenses
VI	1990 to present	Modern capsular posterior chamber lenses and modern anterior chamber lenses

<sup>†</sup>Deceased

Although many surgeons worked on the concept of this type of lens, Baron, in France, is generally credited as being the first designer and implanter of an anterior chamber lens (Fig. 5.2.2A).<sup>10</sup> He first performed this procedure on May 13, 1952.

Late endothelial atrophy, corneal decompensation, and pseudophakic bullous keratopathy were observed with the original Baron lens and developed with many subsequent anterior chamber lens designs. The entity now termed uveitis–glaucoma–hyphema (UGH) syndrome was described first when ocular tissue damage occurred that was clearly the result of

poorly manufactured anterior chamber lenses.<sup>13</sup> It took many modifications of the haptic-loop configuration and the lens-vaulting characteristics (see Fig. 5.2.2B) to develop an anterior chamber lens that allowed a reasonable prediction of long-term success. This was achieved largely because of the advances in lens design by Choyce of England and later by Kelman of New York.

### Generation III (Iris-Supported Lenses)

Relatively frequent dislocation of the Ridley lens and an unacceptably high rate of corneal decompensation associated with the anterior chamber lenses that were available in the early 1950s caused some surgeons to discontinue implantation of IOLs entirely.<sup>14</sup> However, iris-supported or iris-fixated IOLs were introduced subsequently in an attempt to overcome these problems.

Binkhorst in the Netherlands was an early advocate of iris-supported IOLs.<sup>11,12</sup> His first lens was a four-loop, iris-clip IOL (Fig. 5.2.3A) design. Although Binkhorst initially believed that IOL contact with the iris would not cause problems, he soon noted that iris chafing, pupillary abnormalities, and dislocation developed with the early iris-clip lens. Also, in an effort to circumvent dislocation, Binkhorst made the anterior loops of his four-loop lens longer, but this led to increased corneal decompensation from peripheral touch.

His initial implantations were done after ICCE, but occasionally he implanted his four-loop lens following ECCE. His positive experience with this procedure prompted him to modify his iris-clip lens design for implantation following ECCE. Binkhorst's change from ICCE to ECCE and the introduction of his two-loop iridocapsular IOL (see Fig. 5.2.3B) in 1965 were important advances in both IOL design and mode of fixation.<sup>15</sup> His and others' experiences with the two-loop lens style and its modifications were influential in the development of modern design concepts of IOLs, including capsular bag–fixated, posterior chamber IOLs. Binkhorst's innovative lens designs and his advocacy of ECCE came at a time when the entire future of IOL implantation was in jeopardy; they provided the major impetus that set the stage for modern posterior chamber lens implantations.

**Fig. 5.2.1 Posterior View of an Eye (Obtained Postmortem) Showing the Implantation Site of a Ridley Lens.** To the time of death, almost 30 years after implantation, the patient's visual acuity remained 20/20 (6/6) in both eyes. Note the good centration and clarity of the all-polymethyl methacrylate optic in the central visual axis. The lens was implanted by Dr. W. Reese and Dr. T. Hammdi of Philadelphia.

**Fig. 5.2.2 Sagittal Section of the Anterior Segment of the Eye.** (A) The original 1952 Baron anterior chamber lens with fixation in the angle recess. Because this one-piece lens was rigid, sizing problems were unavoidable. Note the extremely steep anterior curvature of the lens. Such excessive anterior vaulting invariably caused corneal endothelial problems. (B) Placement of a modern anterior chamber lens fixated in the angle recess. Note the more subtle anterior vaulting of the loops and lens optic.

**Fig. 5.2.3 Binkhorst Iris-Clip Lenses.** (A) A correctly positioned Binkhorst four-loop, iris-clip lens, well centered in an eye that had good visual acuity. Moderate pupillary distortion and sphincter erosion occur. Note the iris fixation suture superior to the site of the large iridectomy. (B) Posterior view of an autopsy globe that contains a two-loop iridocapsular intraocular lens. Note the rod that helps to secure the lens to the iris through the iridectomy. An outer Soemmerring's ring is present, but the visual axis remains clear. The optic is well centered.

During the early years of iris-fixated IOLs, many clinical and subclinical problems emerged, such as dislocation, pupillary deformity and erosion, iris atrophy with transillumination defects, pigment dispersion, uveitis, hemorrhage, and opacification of the media. Many of these complications were the result of chronic rubbing or chafing of the iris by IOL loops or haptics. Problems were especially severe with metal loop IOLs and occurred frequently with multiple-looped lenses because uveal contact and chafing against the mobile iris tissues were unavoidable with these designs.

An increased incidence of corneal edema occurred in association with iris-supported lens designs. Corneal decompensation and pseudophakic bullous keratopathy became major indications for penetrating keratoplasty. The well-known coexistence of pseudophakic bullous keratopathy and cystoid macular edema (CME) has been termed corneal-retinal inflammatory syndrome by Obstbaum and Galin.<sup>16</sup> Binkhorst's return to ECCE, with the introduction of his two-loop iridocapsular lens in 1965 (see Fig. 5.2.3B),<sup>17</sup> brought about an almost immediate reduction in the incidence of many of these complications.

Most iris-supported lenses were biplanar, with the optic placed in front of the pupil. In general, biplanar IOLs required a larger limbal wound opening for insertion. The change to capsular fixation after ECCE provided better stability for the pseudophakos. This important modification was a forerunner to capsular sac (in-the-bag) fixation of modern posterior chamber IOLs.

At the time when iris-supported lenses were in widespread use, and until the mid-1980s in many cases, manufacturing methods and surgical techniques were less sophisticated. It is now clear that most modern, high-quality anterior and posterior chamber IOLs provide better success than the IOLs that depend on the iris for support. At present, it is the consensus of surgeons that lens explantation and/or exchange is usually the best treatment when a patient who has an iris-supported IOL develops late complications such as inflammation or corneal decompensation that does not respond rapidly to conservative therapy.

## Generation IV (Intermediate Anterior Chamber Lenses)

As iris-supported IOLs underwent major modifications from the early 1950s up to the beginning of the 1980s, several designs of anterior chamber IOLs were introduced.

The problems of tissue chafing and difficulties in correct sizing associated with rigid IOLs were addressed by the development of anterior chamber lenses with more flexible loops or haptics (Box 5.2.1). Unlike the ill-fated, nylon-looped lenses introduced by Dannheim in the early 1950s, the fixation elements of these anterior chamber IOLs were made from more stable polymers, usually PMMA and polypropylene. The best lenses were the various rigid<sup>18</sup> and flexible, open-loop, one-piece PMMA designs, such as the three- and four-point fixation Kelman IOLs.<sup>19</sup> Modifications of the latter have been in use since the late 1970s and are the styles most commonly implanted today (Fig. 5.2.4). These lenses now are well designed, correctly vaulted, and properly sized and can provide excellent long-term results. As with the early generation of anterior chamber IOLs, new lens designs included both haptic (footplate) fixation lenses and small-diameter, round-looped IOLs.

Although in the 1950s implantations with early anterior chamber IOLs were often disappointing, some models of anterior chamber lenses provided good success, particularly when the lens was properly sized. Two important factors that led to a higher success rate with anterior chamber IOL use are improved lens designs and manufacturing techniques.

More appropriate lens flexibility has decreased the need for perfect sizing. Increased attention has been given to the anterior-posterior vaulting characteristics of IOLs, which has reduced the incidence of intermittent touch and uveal chafing problems. Design flaws in older lens styles have been identified and these lenses removed from the market in the United States. Tumble polishing of IOLs, particularly one-piece, all-PMMA lenses, produces excellent surfaces and edges. The elimination of sharp optic or haptic edges is critical in the production of anterior chamber IOLs. This is even more true than for posterior chamber IOLs, because anterior chamber IOLs are fixated in a confined space directly adjacent to delicate anterior segment tissues.

The two major disadvantages of an anterior chamber IOL, as compared with posterior chamber lens styles, are:

- The close proximity of the haptics or loops to delicate tissues such as the trabecular meshwork, corneal epithelium, angle recess, and anterior iris surface.

**Fig. 5.2.4 Modern One-Piece, All-Polymethyl Methacrylate, Kelman-Style Anterior Chamber Lenses of Four-Point and Three-Point Fixation Designs.** Note the excellent polishing and tissue-friendly Choyce-Kelman-style footplates. These represent modern, state-of-the-art lenses that should be distinguished clearly from the earlier, unsatisfactory, closed-loop anterior chamber lenses.

### BOX 5.2.1 Anterior Chamber Lenses

#### Disadvantages of Closed-Loop Anterior Chamber Lenses

- Lenses may be difficult to size
- Lenses may have inappropriate vault-compression ratios; when a lens is compressed, it may vault anteriorly or posteriorly—either type of response can cause deleterious effects
- Small-diameter loops may cause a “cheese-cutter” effect, particularly if the lens is too large; subsequent erosion and chafing can cause uveitis, including cystoid macular edema and pseudophakic bullous keratopathy
- Some lenses have a large contact zone over broad areas of the angle with the potential for secondary glaucoma
- The poorly finished, sharp edges of some lens models can cause chafing, which leads to sequelae such as uveitis or uveitis–glaucoma–hyphema syndrome
- Synechiae formation around the small-diameter loops may make the lens difficult to remove when necessary; tearing of ocular tissues, hemorrhage, and iridocyclodialysis are possible complications of intraocular lens removal if correct procedures are not used

#### Advantages of Modern, Open-Loop, One-Piece, All-PMMA Flexible Anterior Chamber Lenses

- Most modern lenses have an excellent finish with highly polished smooth surfaces and rounded edges from tumble polishing; tissue contact with any component of these intraocular lenses is much less likely to result in chafing damage
- Sizing is less critical with flexible, open-loop designs
- In contrast to a closed-loop anterior chamber intraocular lens, the vault (a well-designed, open-loop lens) is maintained even under high compression—this minimizes intraocular lens touch against the cornea anteriorly or against the iris posteriorly
- Point fixation is possible, since the haptic may subtend only small areas of the angle outflow structures
- Most open-loop intraocular lens designs are much easier to remove, when necessary, especially those with Choyce-like haptic or footplate fixation; the well-polished surfaces of these lenses usually do not become completely surrounded by goniosynechiae or cocoon membranes and thus can usually be removed if necessary without undue difficulty or excessive tissue damage

- The difficulty often encountered in IOL sizing, particularly with rigid lens designs.

The close proximity of anterior chamber lens components to the corneal endothelium is an obvious disadvantage because of the potential for corneal decompensation and/or pseudophakic bullous keratopathy as a

result of contact of the cornea with the IOL. In the past, the most common causes of pseudophakic bullous keratopathy were related to anterior chamber IOLs that were sized incorrectly, vaulted too steeply, or designed with an inappropriate amount of flexibility.<sup>20</sup>

Haptics or spatula-like footplates are one of the two types of fixation elements used for anterior chamber IOLs. Haptics or footplates, popularized by Peter Choyce, are often likened to the flattened portion of a spatula and were used originally with the more rigid IOL styles. They now are used with both rigid and flexible modern anterior chamber IOLs. When IOL removal is necessary for any reason, the footplate generally slides out of the eye much more easily than does a small-diameter loop and does so with minimal tissue damage.

Small-diameter lens loops are the second type of fixation element for anterior chamber IOLs. Loops may be of either an open or a closed design. Round, small-diameter, closed loops may cause a “cheese-cutter” effect within the eye and difficulty in removal. A 360° fibrouveal encapsulation, or “cocoon,” often forms around such small-diameter, round loops as the loops become embedded in the tissues of the angle recess. If the correct explantation procedure is not used, these adhesions may result in tissue tears, hemorrhage, and iridocyclodialysis. These anterior chamber IOLs,<sup>21–25</sup> often generically classified together as “closed-loop lenses,” do not provide the safety and efficacy achieved by other anterior chamber lens designs, such as finely polished, flexible, one-piece, all-PMMA lenses (see Fig. 5.2.4). By 1987 the U.S. Food and Drug Administration had placed IOLs of the closed-loop design on core investigational status. This had the effect of removing them from the market in the United States, although it did not prevent the export of such lenses.

The flexible, open-loop designs,<sup>24–28</sup> modifications of the original Kelman anterior chamber IOLs (with Choyce-style footplates), can be well finished using tumble polishing, which provides a rounded, “tissue-friendly” surface at points of haptic contact with delicate uveal tissues. One-piece IOLs, particularly those with a footplate design, are usually much easier to explant than IOLs with round, small-diameter loops of either closed-loop or open-loop design.

Iris- or scleral-fixated, sutured posterior chamber IOLs may be used in cases formerly reserved for anterior chamber IOLs. Results are encouraging.<sup>29,30</sup> Uncertainty still exists as to whether a retropupillary lens is superior to a modern, well-manufactured, Kelman-style anterior chamber IOL for cases such as intraoperative capsular rupture or vitreous loss or as a secondary or exchange procedure. The technique is more difficult than insertion of a single anterior chamber lens, and therefore it should be carried out only by an experienced surgeon.

## Generation V (Improved Posterior Chamber Lenses)

The return to Ridley's<sup>4–7</sup> original concept of IOL implantation in the posterior chamber occurred after 1975. Pearce<sup>31</sup> of England implanted the first uniplanar posterior chamber lens since Ridley.<sup>32</sup> This lens was a rigid tripod design with the two inferior feet implanted in the capsular bag and the superior foot implanted in front of the anterior capsule and sutured to the iris. Shearing<sup>33</sup> of Las Vegas introduced a major lens design breakthrough in early 1977 with his posterior chamber lens. The design consisted of an optic with two flexible, J-shaped loops. Simcoe of Tulsa publicly introduced his C-looped posterior chamber lens shortly after Shearing's J-loop design appeared. Arnott of London was an early advocate of one-piece, all-PMMA posterior chamber IOLs. The flexible open-loop designs (J-loop, modified J-loop, C-loop, or modified C-loop) still account for the largest number of IOL styles available today (Fig. 5.2.5).

One obvious major theoretical advantage that a posterior chamber IOL has over an anterior chamber IOL is its position behind the iris, away from the delicate structures of the anterior segment.

As posterior chamber lens implantation evolved, the type of fixation achieved in the early years depended largely on chance or on the surgeon's individual preference. As Fig. 5.2.6 illustrates, several loop-fixation sites are possible with modern, flexible-loop posterior chamber IOLs. In general, the loops were anchored in one of three ways:

- Both loops were placed in the ciliary region.
- Both loops were placed within the lens capsular sac.
- One loop (usually the leading or inferior loop) was placed in the capsular sac and the other loop (usually the trailing or superior loop) in a variety of locations anterior to the anterior capsular flap.

These fixation sites have been confirmed histologically by analyses of postmortem globes implanted with posterior chamber IOLs.

**Fig. 5.2.5 View From Behind an Autopsy Eye.** (A) A Sinskey-style, J-loop posterior chamber intraocular lens implanted within the lens capsular bag. The optic is well centered, the visual axis is clear, and there is only minimal regeneration of cortex in scattered areas. Moderate haziness or opacity occurs at the margins of the anterior capsulotomy, which does not encroach on the visual axis. (B) The placement of the loop of this modified C-style intraocular lens in the capsular bag.

The return to posterior chamber lenses coincided with the development of improved ECCE surgery. Shearing<sup>33</sup> identified four major milestones that have marked the evolution of ECCE surgery:

- Microscopic surgical techniques.
- Phacoemulsification (phaco).
- Iridocapsular fixation.
- Flexible posterior chamber lenses.

Without microscopic surgery, modern IOL implantation would be far more difficult. Although phaco was promoted originally because it required only a small wound, it became clear that if an IOL were to be inserted, the wound would have to be enlarged after removal of the cataract, and thus nonultrasonic surgical methods were refined. By 1974, implantation of IOLs again began to achieve significant acceptability. A natural marriage between phaco and implantation of IOLs occurred.

As noted previously, Binkhorst<sup>11,12,17</sup> was one of the pioneers in the return to the ECCE procedure. Binkhorst recognized that an intact posterior capsule enhanced stability, and he also recognized the many advantages of IOL implantation within the capsular sac. Evidence continues to accumulate that CME and retinal detachment occur less frequently with ECCE than with ICCE.

The introduction of flexible posterior chamber lenses designed to be implanted following ECCE largely resolved the debate about ECCE versus ICCE clearly in favor of the extracapsular procedure.

Securing both loops in the lens capsular sac is the only type of fixation in which IOL contact with uveal tissues is avoided.<sup>34</sup> Placement of a lens

**Fig. 5.2.6 The Possible Placement Sites of Posterior Chamber Lens Loops.**

### BOX 5.2.2 Advantages of Placing Both Loops in the Lens Capsular Sac

Intraocular lens is positioned in the proper anatomical site  
 Both loops can be placed symmetrically in the capsular sac as easily as in the ciliary sulcus  
 Intraoperative stretching or tearing of zonules by loop manipulations in front of the anterior capsular leaflet is avoided  
 Low incidence of lens decentration and dislocation  
 No evidence of spontaneous loop dislocation  
 Intraocular lens is positioned a maximal distance behind the cornea  
 Intraocular lens is positioned a maximal distance from the posterior iris pigment epithelium, iris root, and ciliary processes  
 Iris chafing (caused by postoperative pigment dispersion into the anterior chamber) is reduced  
 No direct contact by, or erosion of, intraocular lens loops or haptics into ciliary body tissues  
 Chronic uveal tissue chafing is avoided, and the probability of long-term blood–aqueous barrier breakdown is reduced  
 Surface alteration of loop material is less likely  
 Intraocular lens implantation is safer for children and young individuals  
 Posterior capsular opacification may be reduced  
 Intraocular lens may be easier to explant, if necessary

with one or both loops outside the capsular bag is associated with various potential complications, including decentration and uveal erosion.<sup>34,35</sup> The consequences of uveal touch have been learned after experiences with the earlier iris-fixed IOLs. The excellent success rate now achieved with posterior chamber IOL implantation is associated with improved IOL designs and improved surgical techniques, including the meticulous placement of loops (Box 5.2.2).

Posterior capsule opacification (PCO; Elschnig pearls, secondary or after cataract) is a significant postoperative complication in IOL implantation. A well-designed posterior chamber lens in the lens capsular sac provides a gentle but taut radial stretch on the posterior capsule. Of the present open-loop flexible IOLs, the one-piece, all-PMMA posterior chamber designs with posterior convex or biconvex optics appear to be especially effective in providing a symmetrical stretch. Symmetrical stretch may help minimize PCO, as it reduces the folds in the capsular sac and holds the

**Fig. 5.2.7 Surgeon's View (Cornea and Iris Removed) of a Porcine Eye Showing the Capsulorrhexis Procedure.** Notice the smooth edges of the anterior capsular tear, which is the key feature of this procedure.

posterior capsule firmly against the posterior surface of the IOL optic. This is sometimes termed the "no space, no cells" concept.

The quality of surgery and the accuracy of loop placement are important factors that affect the outcome of the cataract operation. Two very helpful tools are available to surgeons that make precise loop or haptic placement possible:

- Ophthalmic viscosurgical devices (OVDs).
- New methods to control the size, shape, and quality of the anterior capsulotomy.
- The intercapsular (envelope) technique and its successor, circular continuous tear capsulorrhexis, greatly increase the ability to achieve accurate and permanent loop placement.

### Generation VI (Modern Capsular Lenses—Rigid PMMA, Soft Foldable, and Modern Anterior Chamber)

By the end of the 1980s, clinical laboratory studies demonstrated clearly that cataract surgical techniques and IOL design and manufacture had shown remarkable advances.<sup>36–40</sup> Surgical technique and IOL design and manufacture had advanced to a point at which the older techniques had given way to more modern ones, which allowed consistent, secure, and permanent in-the-bag (capsular) fixation of the pseudophakos. A marriage between IOL design and improved surgical techniques has evolved into capsular surgery. The "capsular" IOLs are fabricated from both rigid and soft biomaterials.

The many changes in surgical techniques that occurred after 1980 and into the 1990s include the introduction of OVDs,<sup>40–43</sup> increased awareness of the advantages of in-the-bag fixation, the introduction of continuous curvilinear capsulorrhexis (CCC)<sup>44–51</sup> (Fig. 5.2.7), hydrodissection<sup>52</sup> (Fig. 5.2.8), and the increased use of phaco. This has allowed not only much safer surgery but also implantation through a smaller incision than was possible in the early days of extracapsular extraction.

The evolution from can-opener toward capsulorrhexis (see Fig. 5.2.7) was initiated by Binkhorst, who developed a two-step (envelope) technique that eventually evolved into the single-step CCC. Two clear advantages of CCC exist over the early can-opener techniques.

First, the formation of radial tears (Fig. 5.2.9) is reduced,<sup>47</sup> which minimizes radial tears of the anterior capsule, which in turn reduce the stability of the capsular bag and may allow prolapse of haptics out of the capsular bag through the anterior capsular tear. Second, and less commonly recognized, capsulorrhexis provides a stable capsular bag that allows copious hydrodissection, which in turn is very helpful in cortical cleanup. With a frayed, emptier capsular edge, such as seen with the can-opener technique, hydrodissection is difficult without forming unwanted radial tears.

Hydrodissection (see Fig. 5.2.8) was a term coined by Faust<sup>52</sup> in 1984. This technique, and the many variations thereof (e.g., cortical cleavage hydrodissection, hydrodelineation), makes the surgery much simpler in that mobilization and removal of cells and cortical material are rendered much easier. The long-term risk of PCO is, in turn, clearly minimized

**Fig. 5.2.8** Surgeon's View (Cornea and Iris Removed) of a Human Eye (Obtained Postmortem) Showing Experimental Hydrodissection. In this case the cannula is placed immediately under the anterior capsule (cortical cleavage hydrodissection). Hydrodissection is one of the most important maneuvers to help reduce the incidence of posterior capsular opacification.

**Fig. 5.2.9** Surgeon's View of an Experimentally Performed Can-Opener Capsulectomy, With Typical Radial Tears to the Equator of the Anterior Capsule. The cornea and iris are removed from a human eye obtained postmortem. Following clinical can-opener anterior capsulectomy, one to five radial tears invariably occur. (Reproduced with permission from Assia EI, Apple DJ, Tsai JC, et al. The elastic properties of the lens capsule in capsulorrhexis. *Am J Ophthalmol* 1991;111:628–32.)

because of the more thorough removal of cells in cortical material, especially in the region of the equatorial fornix.

Modern phaco, pioneered by Kelman, has now made possible the removal of lens material through small incisions and the implantation of IOLs through incisions down to 3 mm in length, as opposed to incisions of 11 to 12 mm length in the early days of ECCE. Many real advantages of small-incision cataract surgery exist, including safer healing (with fewer risks of complications such as inflammation), more rapid healing, and rapid recovery of visual rehabilitation (with less postoperative astigmatism).

Accompanying the developments of surgical techniques that allow secure in-the-bag implantation, IOLs have evolved that work well with these techniques—both rigid PMMA designs (Figs. 5.2.10 and 5.2.11) and foldable IOLs.<sup>53</sup> Fig. 5.2.10 shows an example of a modern, state-of-the-art, one-piece, all-PMMA IOL that is designed for in-the-bag implantation. These can be inserted through incisions as small as 5.5–6 mm in length and provide an excellent alternative for the surgeon who finds the almost 50-year history of PMMA as a lens biomaterial of comfort. Long-term results with these IOLs are excellent and, indeed, these lenses provide slightly better centration than do some of the more modern foldable lenses at the present time. The ideal diameter for a one-piece IOL design such as that in Fig. 5.2.10 is 12–12.5 mm, which allows it to fit perfectly into the

**Fig. 5.2.10** A Modern, One-Piece, All-PMMA, Capsular IOL Implanted Experimentally in a Human Eye: Posterior View (Miyake Technique) of the Eye (Obtained Postmortem). Note the excellent centration and a perfect fit within the capsular bag.

**Fig. 5.2.11** Scanning Electron Micrograph of a Well-Designed, Tumble-Polished, Modified C-Loop, One-Piece, All-PMMA Posterior Chamber IOL. The total length of this capsular IOL design is 12.0 mm. Note the excellent, smooth finish of this well-polished IOL. (Original magnification  $\times 10$ .)

capsular bag (which measures about 10.5 mm in diameter). The diameter of the ciliary sulcus is only slightly larger (approximately 11.0 mm)<sup>53</sup> and actually decreases with age.

These rigid PMMA IOL designs have been found to be very satisfactory in pediatric IOL implantation.<sup>54,55</sup> As 90% of the growth of the infantile globe occurs during the first 18 months to 2 years (Fig. 5.2.12), it is fair to assume that “adult” 12 mm lenses can be safely implanted with the achievement of good results in children of this age and older (Figs. 5.2.12 and 5.2.13). The problem in the past with IOL implantation has been that of PCO. With present techniques, this is best prevented using primary posterior capsulectomy.

Improved small-incision surgical techniques and IOL designs have resulted in a natural evolution toward foldable lenses.<sup>56–67</sup> Most foldable lenses today are manufactured from silicone, hydrogel, or acrylic material (Figs. 5.2.14–5.2.16).

The earliest designs for which clinical usage was widespread were the plate lenses known as the “Mazzocco taco.” In early years these were manufactured poorly and often not implanted properly into the capsular bag, so many complications ensued. In recent years manufacturing quality has become much better, and these lenses are now satisfactory for clinical usage (Figs. 5.2.17 and 5.2.18). The best plate lenses are those with large positioning holes that allow in-the-bag synechia formation, which enhances fixation and stability.<sup>64</sup>

**Fig. 5.2.12 Growth of the Globe and Lens Capsular Bag.** These results are based on a study of 50 eyes obtained postmortem and demonstrate that the growth of the globe and lens capsular bag occurs relatively rapidly during the first 18 months to 2 years. (A) Miyake–Apple posterior photographic technique. The arrow indicates the fibrotic tissue growing through one of the large fenestrations. (B) Fusion between anterior and posterior capsules promoted by the fibrocellular tissue growing through the fenestration (Masson's trichrome; original magnification  $\times 100$ ). PC, Posterior capsule. (Reproduced from Apple DJ, Auffarth GU, Peng Q, et al. Foldable intraocular lenses: evolution, clinicopathologic correlations, complications. Thorofare, NJ: Slack; 2000.)

The most commonly implanted designs at present are three-piece lenses that consist of silicone, acrylic, or hydrogel optics. Plate lenses continue to provide excellent results. These lenses can be implanted through incisions smaller than 5 mm in length. Visual rehabilitation is now incredibly fast with various further modifications, such as clear corneal incisions and topical anesthesia. Such surgery is virtually analogous to arthroscopy of the eye.

Lens design and manufacture have improved to such an extent that perhaps the most important factor in achieving a successful result is not the IOL itself, but the quality of surgery. These factors are very important now that high standards exist for results following IOL implantation, especially in this era, when IOL implantation is considered not only a means of optical rehabilitation after cataract removal but also a bona fide refractive procedure. The development of bi- and multifocal IOL designs is one example of this evolutionary process. An increased interest in clear lens extraction for myopia and the use of phakic IOLs also exemplifies the evolution toward refractive IOLs. It is of utmost importance to achieve symmetrical capsular bag fixation and good cortical cleanup to minimize the chance of complications, such as lens decentration and formation of a Soemmerring's ring.

The development of foldable lenses is one of fine-tuning. For example, much effort is now being expended to develop ever more tissue-friendly optic biomaterials. Fig. 5.2.19 reveals a complication that may occur occasionally in patients who have silicone lenses and who require subsequent

vitreoretinal surgery using silicone oil.<sup>68</sup> Work is underway to address this complication by modifications of the biomaterial to change factors such as its surface characteristics.<sup>69</sup> Work is in progress also on the attachment of different styles of haptic materials to the optic to achieve better and more stable fixation of the haptics in the capsular bag.

Note that the various ultramodern designs of anterior chamber lenses developed for both aphakic and phakic implantations are considered to belong to generation VI. These include the various Kelman–Choyce designs and modifications by Baikoff and Clemente (see Fig. 5.2.4). These are categorized here to separate them from the many generally inferior anterior chamber IOLs that were available in the earlier intermediate period between 1963 and 1990 (generation IV). The ultramodern designs are suitable for specific clinical indications and clearly should not be included in the generic concept that all anterior chamber IOLs are bad.

## RECENT ADVANCES

There are some general principles and tendencies with regard to the development of new IOLs.

- Large fixation holes or foramina have been incorporated in the haptic components of one-piece plate designs (Fig. 5.2.20A). Fibrous adhesions often occur between the anterior and posterior capsules following ingrowth of fibrocellular tissue through the holes (Fig. 5.2.20B). This

**Fig. 5.2.21 Light Photomicrograph and Schematic Illustration Showing the Barrier Effect of an IOL Optic With a Square Truncated Edge.** (A) Photomicrograph of a case in which the Soemmerring's ring (red) remains totally confined to the right of the square optic edge, leaving the posterior capsule (lower left) cell free (Masson's trichrome; original magnification  $\times 50$ ). (B) Square truncated optic edge seems to provide an abrupt barrier (arrows), leaving the entire optical zone free of cells. AC, Anterior capsule; PC, posterior capsule. (A, Reproduced from Werner L, Apple DJ, Pandey SK. Postoperative proliferation on anterior and equatorial lens epithelial cells. In: Buratto L, Werner L, Zanini M, et al., editors. Phacoemulsification: principles and techniques. Thorofare, NJ: Slack; 2002. p. 603–23. B, Reproduced from Peng Q, Visessook N, Apple DJ, et al. Surgical prevention of posterior capsule opacification. Part III. Intraocular lens optic barrier effect as a second line of defense. J Cataract Refract Surg 2000;26:198–213.)

**Fig. 5.2.22 Gross and Light Microscopy Photographs of the First Human Eye Obtained Postmortem With a Single-Piece AcrySof Lens (Alcon Laboratories, Fort Worth, TX) Accessioned in Our Center.** (A) The lens is well centered and the capsular bag is clear. (B) Light photomicrograph of a histological section from the same eye. The arrow indicates the imprint of the square edge of the lens optic on the capsular bag, causing a barrier effect that prevented retained/regenerative cortical material from the Soemmerring's ring to migrate onto the posterior capsule, opacifying the visual axis (Masson's trichrome; original magnification  $\times 400$ ). (Reproduced from Escobar-Gomez M, Apple DJ, Vargas LG, et al. Scanning electron microscopic and histologic evaluation of the AcrySof SA30AL acrylic intraocular lens. J Cataract Refract Surg 2003;29:164–9.)

helps enhance the fixation and stability of these designs within the capsular bag.<sup>70</sup> It is important to note that this fibrous growth requires at least 2 weeks and often much more to establish itself and help anchor the IOL. This design feature has been incorporated into lenses manufactured from silicone (including the Staar toric IOL), hydrogel (hydrophilic acrylic IOLs), and Collamer (Staar CC4203VF) materials.

- For three-piece foldable designs, the preferred haptic materials are the relatively rigid materials with good material memory, such as PMMA, polyimide (Elastimide), or poly(vinylidene) fluoride (PVDF).<sup>71</sup> These haptics have appropriate memory characteristics that help enhance lens centration and stability and provide better resistance to postoperative contraction forces within the capsular bag.
- One of the most important features that has been incorporated in new foldable lenses in terms of decreasing the incidence of PCO is the square, truncated optic edge. Various experimental animal studies by Nishi in Japan, analyses of human autopsy globes in our laboratory, and several clinical studies with the three-piece AcrySof lens (MA30BA and MA60BM)—the first design identified with this geometric

characteristic—demonstrated an enhanced barrier effect against cell migration/proliferation on the posterior capsule toward the visual axis (Fig. 5.2.21).<sup>72,73</sup>

- Manufacturers have invested heavily and with great success in single-piece designs, all fabricated from the same material as the optic component. The Alcon (SA30AL and SA60AT) AcrySof IOL is a hydrophobic single-piece acrylic design that has provided excellent results (Fig. 5.2.22). Other looped single-piece designs are now available, with modifications at the level of the optic–haptic junctions to obtain a non-smooth transition between these components. This was done because some studies demonstrated that smooth optic–haptic junctions may be sites for PCO initiation.<sup>74</sup>
- Manufacturers also are investing in the development of injector systems to be used with the new lens designs. Other recent advances are represented by the development of injector systems where the IOLs come preloaded and by automated injection systems.
- Perhaps the most energy and funding are being spent on new and complex IOLs that not only restore the refractive power of the eye after

**Fig. 5.2.23 Special Intraocular Lenses.** (A) Gross photograph of a toric lens (AA-4203TF or AA-4203TL Staar Surgical, Inc.) This lens has basically the same design as single-piece, plate silicone posterior chamber lenses with large fenestrations but with an incorporated cylindrical correction. (B) Schematic drawing representing an accommodative lens, the Crystalens, manufactured by Bausch & Lomb (Rochester, NY). This is essentially a plate haptic lens with Elastimide haptics. It is stated that redistribution of the ciliary body mass during effort for accommodation will result in increased vitreous pressure, which will move the optic of this lens anteriorly within the visual axis, creating a more plus powered lens. (C) Schematic drawing representing the implantable miniaturized telescope (IMT) (VisionCare Ophthalmic Technologies Inc., Yehud, Israel). This is designed specifically to improve vision of patients suffering from age-related macular degeneration. The IMT is composed of two parts, an optical cylinder and a carrying device. The optic cylinder is made of pure glass. The carrying device is made of black PMMA. The latter has a general configuration of a posterior chamber intraocular lens, with two modified C-loops or haptics that hold the device in the capsular bag. Once in place, the anterior part of the optic extends anteriorly for approximately 1 mm through the pupil. It is designed to be stabilized approximately 2 mm posterior to the corneal endothelium. (A–C, Reproduced from Werner L, Apple DJ, Schmidbauer JM. Ideal IOL (PMMA and Foldable) for year 2002. In: Buratto L, Werner L, Zanini M, et al., editors. Phacoemulsification: principles and techniques. Thorofare, NJ: Slack; 2002. p. 435–52.)

cataract surgery but also provide special features, including multifocality, extended depth of focus, toric corrections (Fig. 5.2.23A), pseudoaccommodation (Fig. 5.2.23B), asphericity, postoperative adjustment of the IOL refractive power, image magnification (telescopic lenses) (Fig. 5.2.23C), protection of the retina against blue or violet light (through incorporation of appropriate chromophores to the IOL optic material), or those that can be inserted through sub 2.0 mm incisions.<sup>75</sup>

Itemization of these IOL designs is not yet useful because proof of safety and efficacy is still in great flux. With any IOL, the issue of biocompatibility must be assessed. Not only do surgeons today seem to be seeking IOLs that are easy to insert/inject through small incisions—perhaps the main factor influencing manufacturers' IOL development—but also more attention is being paid to the interaction of each IOL design within the surrounding capsular bag. Issues such as postoperative cell proliferation within the capsular bag—including PCO, anterior capsule opacification (ACO), and interlenticular opacification (ILO) with piggyback IOLs—are used as one indication of lens biocompatibility.<sup>76,77</sup> This goes far beyond the normal postoperative inflammatory reaction observed after cataract surgery with IOL implantation. Different studies from our laboratory demonstrated that the choice of IOL design and material can largely influence the outcome of these complications, but the role of surgical techniques should not be underestimated. Last but not least, a “perfect” IOL would not be effective in preventing excess cell proliferation within the capsular bag after bad surgery.

- The renewed interest in phakic IOLs, which we now realize can potentially correct any refractive error, is also progressing rapidly.<sup>78</sup> It is somewhat ironic that anterior chamber IOLs, previously relegated by many surgeons to a wastebasket of discarded devices, have been resurrected and researched as a possible lens of choice for refractive correction. Most of the angle-supported anterior chamber phakic IOLs, however, have been abandoned from the market due to issues with the corneal endothelium.<sup>79</sup> Lenses designed for iris fixation and placement in the posterior chamber are also available, with good results to date. There is a trend for the use of foldable materials for these phakic lenses, which are designed to be inserted through small incisions (Fig. 5.2.24).
- There is a renewed interest in the piggyback IOL procedure, not only for correction of residual refractive errors but also because of the potential to implant a low-power multifocal lens to provide spectacle freedom to patients who already are pseudophakic, and other specialized lenses such as toric and aspherical IOLs. In these cases, the supplementary lens is fixated in the ciliary sulcus to avoid ILO formation. A supplementary IOL for implantation in the sulcus ideally should be manufactured from a soft, biocompatible material, with a relatively large optic and overall diameters, as well as round and smooth optic and haptic edges. Also, the design configuration should provide appropriate clearance with uveal tissues and the in-the-bag IOL (Fig. 5.2.25).<sup>80</sup>

Although a large spectrum of lenses is available today, the IOL of choice still depends on a surgeon's personal preference based on multiple factors

**Fig. 5.2.24 Drawing (A) and Clinical (B) and Gross (C) Photographs Showing Different Types of Phakic Lenses.** (A) Cachet lens (Alcon Laboratories, Fort Worth, TX, USA). It has a 4-haptic, angle-supported configuration, manufactured from the same hydrophobic acrylic material as posterior chamber AcrySof lenses. (B) Artisan lens (Ophtec, Groningen, the Netherlands). This is a one-piece, iris-fixed lens manufactured from PMMA. Artisan haptics (fixation arms) attach to the midperipheral, virtually immobile iris stroma, thus allowing relatively unrestricted dilation and constriction of the pupil. Lenses with incorporated cylindrical correction and a foldable version (silicone optic) are also available. (C) Implantable contact lens (ICL) (Staar Surgical). This is a one-piece plate lens manufactured from a proprietary hydrophilic collagen polymer known as Collamer. It can be inserted or injected into the anterior chamber, then the haptics are placed behind the iris with the help of a spatula. (A, Courtesy Alcon Laboratories. B and C, Reproduced from Werner L, Apple DJ, Izak AM. Phakic intraocular lenses: current trends and complications. In: Buratto L, Werner L, Zanini M, et al., editors. Phacoemulsification: principles and techniques. Thorofare, NJ: Slack; 2002. p. 759–77.)

**Fig. 5.2.25 Pseudophakic Human Eye Obtained Postmortem, Experimentally Implanted With the Sulcoflex (Rayner Intraocular Lenses, East Sussex, UK) Supplementary IOL.** The capsular bag containing a standard posterior chamber IOL was removed for gross analysis of the positioning of the Sulcoflex haptics from the posterior or Miyake–Apple view. No disturbances/distortions to the ciliary processes were observed. This lens was designed by Amon in Austria. It is a single-piece, hydrophilic acrylic lens with an optic diameter of 6.5 mm and an overall diameter of 14.0 mm. The optic has round and smooth edges and a convex–concave configuration. The large-diameter undulating haptics are soft with round and smooth edges and a posterior angulation of 10° in relation to the optic.

personalized to each individual, largely influenced by different features unique to each patient, such as the patient's history and clinical status, but also by the occurrence of intraoperative complications.

# Epidemiology, Pathophysiology, Causes, Morphology, and Visual Effects of Cataract

## 5.3

Mark Wevill

**Definition:** The prevalence, distribution, strategies to reduce the cataract prevalence and the disordered physiological processes, causes, and different forms of cataract are discussed.

### Key Features

- Cataracts develop earlier in developing countries, and the cataract surgical rates are lower, resulting in a higher prevalence of cataracts. But improved provision of cataract surgery in some developing nations has significantly reduced cataract prevalence.
- Factors in cataract pathogenesis include lens protein oxidation, mitochondrial function, failure of protective mechanisms, protein modification, and abnormalities of calcium metabolism, cellular proliferation, and differentiation.
- An accumulation of environmental insults (e.g., ultraviolet light, toxins, drugs, and systemic diseases) results in age-related cataracts. Minor risk factors such as ultraviolet B exposure and smoking can be modified.
- Nutritional, pharmacological, and genetic interventions are being investigated.
- Anomalies of lens growth are usually associated with other ocular or systemic disorders.

### EPIDEMIOLOGY OF CATARACTS

In 2010 the Vision Loss Expert Group funded by the Bill & Melinda Gates Foundation, Fight for Sight, and others calculated that cataracts caused blindness (visual acuity in the better eye of less than 3/60) in 10.6 million people and moderate to severe visual impairment (MSVI, visual acuity of between 6/18 and 3/60) in 34.4 million people. However, wide regional variations exist in the prevalence of cataracts. In North America, the prevalence of blindness and MSVI was 0.3% and 0.4%, respectively. In South Asia, the respective prevalence was 2% and 6.8%. Sub-Saharan Africa is similar. However, cataract blindness and MSVI have declined since 1990 due to better provision of cataract surgery. Once again the decline in prevalence shows wide regional variations, with the greatest decline in East Asia, Latin America, and Western Europe, where the prevalence fell by more than half. The region with the least decline was Sub-Saharan Africa.<sup>1</sup>

The world's population is increasing (predominantly in developing countries), and people will live to greater ages. So without accessible, efficient cataract surgery, the prevalence will increase. Developing countries bear an increasing burden for cataract blindness because cataracts occur earlier in life, and the incidence is higher. In India, visually significant cataract occurs 14 years earlier than in the United States, and the age-adjusted prevalence of cataract is three times that of the United States.<sup>2,3</sup> Cataracts are the leading cause of blindness in middle- and low-income countries, accounting for 50% of blindness but cause 5% of blindness in developed countries.<sup>4</sup>

Low-cost small-incision cataract surgery with lens implantation is a proven clinical strategy. The socioeconomic effect of cataract surgery is substantial. It allows people to increase their economic output to 1500% of the cost of the surgery in the first postoperative year, but if left untreated,

it can result in a person being removed from work and dependent on a caregiver who is also removed from work.<sup>4</sup>

The cataract prevalence is influenced by the Cataract Surgical Rate (CSR or number of cataract surgeries performed per million people per year), which varies from less than 200 to over 6000 in different regions. The CSR is determined by the effectiveness of strategies for stimulating demand from patients because of good outcomes and how well easily accessible cataract surgery is delivered.

So a high cataract prevalence rate in some developing countries is not for want of a clinical solution but partially due to ineffective implementation. For example, Sub-Saharan Africa is resource poor with low surgeon productivity (number of procedures done per year). To reduce cataract prevalence, the resource base (infrastructure, equipment, ophthalmologists, and other ophthalmic workers) must improve, as must management of the resources to build the right processes for maximal cost-effective resource utilization. Future solutions will have to address these challenges.<sup>5</sup>

### PATHOPHYSIOLOGY OF CATARACTS

The lens transmits, filters, and focuses light onto the retina. The high refractive index and transparency of the lens is due to the high concentration and orientation of intracellular structural proteins:  $\alpha$ ,  $\beta$ , and  $\gamma$  crystallins. The anterior subcapsular layer of cuboidal lens epithelial cells are nucleated, actively divide, and account for almost all the metabolic activity of the lens. Cuboidal cells in the equatorial zone of the lens undergo oxidation and other biochemical, physiological, and structural changes. The cells elongate into lens fiber cells, lose their intracellular organelles and ability to perform metabolic functions, and form mature lens fibers. Lens fibers migrate toward the nucleus of the lens and are compacted as more fibers are formed around them, resulting in nucleosclerosis and later in opacity.<sup>6,7</sup>

The transparency of the lens is dependent on the regular organization of the lens cells and intracellular lens proteins. The precise mechanisms by which lens proteins both prevent aggregation and maintain lens transparency are largely unknown. Genetic, metabolic, nutritional, and environmental insults and ocular and systemic diseases disrupt cellular organization and intracellular homeostasis, eventually causing light scattering and absorption, which compromise vision. Once damaged, the lens has limited means of repair and regeneration and may lose its transparency by the formation of opaque lens fibers, fibrous metaplasia, epithelial opacification, accumulation of pigment, or formation of extracellular materials. Several interlinked mechanisms for cataract formation have been proposed, and no single theory completely explains age-related cataract (the commonest form).<sup>7</sup> Much is still unknown about cataractogenesis, but many of the important components are becoming clearer.

### Genetics

Many inherited genetic syndromes and metabolic disorders are associated with cataracts, and at least 42 genes and loci have been found to underlie Mendelian inherited forms of isolated or primary cataract. Increasing evidence exists that several genes underlying rare forms of inherited cataract also can influence susceptibility to the much more prevalent forms of age-related cataract. These observations raise the possibility of molecular genetic links between lens development and aging.<sup>8</sup> Age-related cataracts are inherited as a multifactorial or complex trait. Determining the genetics

of age-related cataracts is difficult because only a small proportion of the genes involved have been identified, similar gene mutations result in different cataract phenotypes, and cataract epigenetics is complex.

Epigenetics are heritable changes in the gene expression without changes in the DNA sequence. Most genes involved in cataract formation show decreased expression. DNA methylation and other histone modifications inhibit RNA transcription, effectively silencing gene expression. For example, in age-related cataracts, the gene DNA for the alpha A-crystallin protein is hypermethylated.<sup>9</sup> Therapy targeted at reversing methylation and upregulating RNA transcription may prevent or reduce lens opacities. Genes that preserve lens clarity function in diverse processes including protein synthesis (e.g., structural proteins, chaperones, and cell-cycle-control proteins) and reducing oxidative stress (e.g., glutathione peroxidases). Decreased expression reduces lens epithelial cell stress tolerance and protein synthesis. Increased gene expression also can cause lens opacities, for example, by increasing lens epithelial cell ionic transport (e.g., calcium-ATPase, which controls calcium channels) and extracellular matrix protein production.<sup>10</sup> Identifying more genetic and epigenetic determinants of inherited and age-related cataracts may result in nonsurgical treatments for cataract or lifestyle interventions (e.g., diet) and may prevent or reverse cataract formation.<sup>11,12</sup>

## Cell Proliferation and Differentiation

Aqueous growth factors including fibroblast growth factor (FGF), epidermal growth factor (EGF), insulin-like growth factor (IGF), platelet-derived growth factor (PDGF), and transforming growth factor (TGF- $\beta$ ) promote proliferation, differentiation into lens fibers, and maturation of the lens fibers. These processes will not occur if growth factor or cytokine concentrations are incorrect. Then undifferentiated cells migrate to the posterior pole, causing posterior subcapsular cataracts.<sup>6</sup>

## Metabolic Disturbance and Osmotic Regulation Failure

Altered gene expression changes enzyme growth factor, membrane protein, and other protein levels, which reduces energy production; changes ion transport, calcium metabolism, and antioxidant pathways; and breaks down protective mechanisms.<sup>6</sup> For example, the lens maintains high intracellular potassium and low sodium levels with the opposite extracellular concentrations via the action of the sodium-potassium ATPase pump. Pump inactivation causes increased intracellular osmolality, which results in water accumulation and light scatter.<sup>6</sup>

The aqueous humor is a source of nutrients and mineral ions including calcium ( $\text{Ca}^{2+}$ ).  $\text{Ca}^{2+}$  is an intracellular signal that regulates many functions including the permeability of the cell membranes. The extracellular  $\text{Ca}^{2+}$  concentration is 10 times the intracellular  $\text{Ca}^{2+}$  concentration, which drives  $\text{Ca}^{2+}$  into the epithelial cell. Low intracellular  $\text{Ca}^{2+}$  levels also are maintained by intracellular organelle membrane pumps (on the endoplasmic reticulum, Golgi apparatus, and mitochondria) and by binding to

complex proteins (e.g., crystallins). Extracellular  $\text{Ca}^{2+}$  can be bound to the outer layer of the cell membrane. Reduced binding of  $\text{Ca}^{2+}$  by membrane proteins increases cell membrane permeability and causes a rise in intracellular  $\text{Ca}^{2+}$  levels, the formation of calcium oxalate crystals, binding of  $\text{Ca}^{2+}$  to insoluble lens proteins, increased light scattering, and nuclear cataract formation. Increased intracellular  $\text{Ca}^{2+}$  levels also affect lens epithelial cell differentiation, causing posterior subcapsular cataracts. Corticosteroids have been shown to mobilize intracellular  $\text{Ca}^{2+}$  in other tissues, which can increase  $\text{Ca}^{2+}$  levels. In the future,  $\text{Ca}^{2+}$ -regulating drugs may be developed to prevent cataracts.<sup>13</sup>

## Calpains

The roles of calpains in the lens are poorly understood, but they may degrade accumulated damaged lens proteins. A lack of calpains can lead to elevated levels of damaged proteins, reduce optical performance, and cause cataract. Also, excessive stimulation of calpain activity by raised  $\text{Ca}^{2+}$  levels can increase proteolysis and cause cataracts. Calpain inhibitors, therefore, could be useful in the nonsurgical treatment of cataract. However, calpain inhibitors of high molecular weight are unable to cross membranes, so have been of no therapeutic use, whereas others are poorly water soluble or are toxic to lenses.<sup>14</sup>

## Protein Modification

Additive modifications of lens proteins (e.g., crystallins) include methylation, acetylation, carbamylation, glycation in diabetics, and binding of ascorbate, which may be the cause of lens discoloration. These additions occur especially in disease and can alter the function or properties of a protein. Diabetes (reducing sugars), renal failure (cyanate generated from urea), aging (photooxidation products), and corticosteroid use (ketoamines) have been linked to cataracts. Additive modifications can make proteins more susceptible to photooxidation by ultraviolet (UV) light.<sup>6,15</sup>

Subtractive modifications include cleavage by enzymes (such as calpains) of crystallin that causes precipitation of lens proteins. Cleavage of channel proteins can affect intercellular communication. Neutral modifications such as isomerization can denature proteins, affecting their function. Deamidation changes the charge and affects protein-protein interactions.

Proteins in the center of the lens are as old as the individual and are very stable, but over time they can undergo conformational changes (unfolding) that expose thiol groups, which are usually “hidden” in the folds of the protein (Fig. 5.3.1). The exposed glutathione groups can be oxidized to form disulfide bonds (GSSG), causing aggregation of proteins. The conformation changes and aggregation result in scattering and absorption of light.<sup>15</sup>

## Oxidation

Oxidation is a key feature in the pathogenesis of most cataracts. Low oxygen levels ( $\text{O}_2$ ) are important for maintaining a clear lens. Free radicals and other oxidants, including reactive oxygen species (ROS) and reactive

**Fig. 5.3.1** Conformational changes in lens proteins (unfolding) exposes thiol groups ( $-\text{SH}$ ). Oxidation to disulfides ( $-\text{S}-\text{S}-$ ) causes protein aggregation and scatters light.

nitrogen species (RNS), are derived from both endogenous sources (mitochondria, peroxisomes, endoplasmic reticulum, phagocytic cells, etc.) and exogenous sources (pollution, alcohol, tobacco smoke, heavy metals, transition metals, industrial solvents, pesticides, and certain drugs like halothane, paracetamol, and radiation). Free radicals can adversely affect nucleic acids, lipids, and proteins, altering the normal redox status and leading to increased oxidative stress and cataracts.<sup>15</sup>

A steep oxygen gradient occurs from the outer part of the lens to the center. Mitochondria in the lens cortex remove most of the oxygen, thus keeping nuclear  $O_2$  levels low. However, in older people, mitochondrial function diminishes and superoxide production by the mitochondria increases, resulting in increased nuclear oxygen and superoxide levels. As the lens ages, a lens barrier develops at approximately the cortex–nuclear interface, which impedes the flow of molecules such as antioxidants (including glutathione) into the nucleus. Unstable nuclear molecules such as peroxide ( $H_2O_2$ ), which are generated in the nucleus or which penetrate the barrier, therefore, cause protein oxidation. Also, a lower concentration of antioxidants exists. Decomposition of UV filters in the nucleus also produces unstable reactive molecules that bind to proteins, especially if antioxidant glutathione (GSH) levels are low. Ascorbate becomes reactive with proteins in the absence of GSH. These oxidative changes can be detected even in the earliest cataracts and are progressive. Elevated levels of superoxide  $H_2O_2$  in the aqueous may cause cortical cataracts, since the cortex is closest to the aqueous. Copper and iron are present in higher concentrations in cataract lenses and are involved in redox reactions, which produce hydroxyl radicals.<sup>16</sup>

## Defensive Mechanisms

Antioxidant enzymes and antioxidants such as ascorbate, glutathione, tocopherols, and carotenoids maintain lens proteins in the reduced state and are the primary defense mechanisms. In advanced age-related nuclear cataracts, more than 90% of protein sulfhydryl groups and almost half of all methionine residues in the nuclear proteins become oxidized. Secondary defenses include proteolytic and repair processes, which degrade and eliminate damaged proteins, UV filters, and other molecules such as glutathione reductase and free radical scavenging systems. Failure of these protective mechanisms, a shortage of antioxidants, and increased free radicals result in cell membrane and protein damage.<sup>6,16</sup>

## Other Factors

Crystallins may have a number of functions. For example  $\alpha$ -crystallin may be a chaperone that binds to other lens proteins to prevent precipitation. Decreased crystallin levels cause proteins to precipitate, which leads to cataract formation. Phase separation of proteins refers to the hydrophobic aggregation of lens proteins causing protein rich and poor regions in the lens fibers, which results in light scatter. The lipid composition of the cell membranes also changes with age, which may have functional consequences.

## CATARACT CAUSES, ASSOCIATIONS, AND PREVENTION

### Age

The cumulative effect of many environmental factors (UV light, x-irradiation, toxins, metals, corticosteroids, drugs, and diseases, including diabetes) causes age-related cataracts. Gene expression changes result in altered enzyme, growth factor, and other protein levels. Protein modification, oxidation, conformational changes, aggregation, formation of the nuclear barrier, increased proteolysis, defective calcium metabolism, and defense mechanisms occur with increasing age. Compromised ion transport leads to osmotic imbalances and intercellular vacuolation. Age-related abnormal cellular proliferation and differentiation also produce opacities (Fig. 5.3.2). There is also an increased incidence of diseases such as diabetes that causes cataracts.

### Sunlight and Irradiation

UV-B light causes oxidative damage, which is cataractogenic. The level of free UV filters in the lens decreases with age, and breakdown products of the filters act as photosensitizers that promote the production of reactive oxygen species and oxidation of proteins in the aging lens. The risk of

**Fig. 5.3.2 Age-Related Cataract.** Nuclear sclerosis and cortical lens opacities are present.

cortical and nuclear cataract is highest in those with high sun exposure at a younger age. Exposure later in life was more weakly associated with these cataracts. Wearing sunglasses, especially when younger, has some protective effect.<sup>17</sup> Unfortunately, the risk attributable to sunlight exposure is small,<sup>18</sup> and cortical cataracts are less debilitating than nuclear or posterior subcapsular cataracts. Therefore, reducing sunlight exposure may have a limited benefit in delaying the onset of cataracts. Exposure to high levels of X-rays and whole-body irradiation also causes cataracts.

### Smoking and Alcohol

Smoking causes a threefold increase in the risk of developing nuclear cataracts, and cessation of smoking reduces this risk. Smoking also may be associated with posterior subcapsular cataracts. Smokers are more likely to have a poor diet and high alcohol consumption, which also are risk factors for cataract. Smoking causes a reduction in endogenous antioxidants. Tobacco smoke contains heavy metals such as cadmium, lead, and copper, which accumulate in the lens and cause toxicity. No association between passive smoking and cataract has been demonstrated.<sup>19,20</sup> Alcohol use has little, if any, association with cataract risk, and study reports are mixed.

### Body Mass Index

A number of health-related factors—diabetes, hypertension, and body mass index (BMI)—are associated with various forms of lens opacity, and they may be interrelated. A high BMI increases the risk of developing posterior subcapsular and cortical cataracts.<sup>20</sup> A high BMI also is associated with diabetes and hypertension, which are associated with cataracts. Severe protein-calorie malnutrition is a risk factor for cataracts. Therefore, a moderate calorie intake may be optimal to reduce the risk of developing cataracts.

### Myopia

After controlling for age, gender, and other cataract risk factors (diabetes, smoking, and education), posterior subcapsular cataracts are associated with myopia, deeper anterior chambers, and longer vitreous chambers.<sup>21</sup>

### Trauma

Blunt trauma that does not result in rupture of the capsule may allow fluid influx and swelling of the lens fibers. The anterior subcapsular region whitens and may develop a characteristic flower-shaped pattern (Fig. 5.3.3) or a punctate opacity. A small capsular penetrating injury results in rapid fiber hydration and a localized lens opacity, and a larger rupture results in complete lens opacification. Penetrating injuries can be caused by accidental or surgical trauma such as a peripheral iridectomy or during a vitrectomy.

Electric shocks as a result of lightning or an industrial accident cause coagulation of proteins, osmotic changes, and fernlike, grayish white anterior and posterior subcapsular opacities.<sup>22</sup> Ionizing radiation, such as from X-rays, damages the capsular epithelial cell DNA, affecting protein and

**Fig. 5.3.3 Traumatic Cataract.** (A) Typical flower-shaped pattern with coronary lens opacities. (B) Seen in retroillumination in anterior subcapsular region.

enzyme transcription and cell mitosis. An enlarging posterior pole plaque develops. Nonionizing radiation, such as infrared, is the cause of cataract in glassblowers and furnace workers working without protective lenses. A localized rise in the temperature of the iris pigment epithelium causes a characteristic posterior subcapsular cataract, which may be associated with exfoliation of the anterior capsule.

## Systemic Disorders

In uncontrolled type 1 diabetes mellitus in young people, hyperglycemia causes glucose to diffuse into the lens fiber, where aldose reductase converts it to sorbitol. The cell membrane is impermeable to sorbitol, and therefore it accumulates. The osmotic effect draws water into the lens fibers, which swell and then rupture. The cataract progresses rapidly with the development of white anterior and posterior subcapsular and cortical opacities.

In type 2 diabetic adults, an early onset age-related type of cataract occurs and is more prevalent with longer duration of the diabetes. Many mechanisms are involved and include sorbitol accumulation, protein glycosylation, increased superoxide production in the mitochondria, and phase separation. During hyperglycemia, glucose is reduced to sorbitol, depleting antioxidant reserves, and less glutathione is maintained in the reduced form, which causes other oxidative damage. Levels of lens  $\text{Ca}^{2+}$  also are elevated, which activates calpains, causing unregulated proteolysis of crystallins. The cataracts are usually cortical or posterior subcapsular or, less frequently, nuclear and progress more rapidly than age-related cataract.<sup>23,24</sup>

Galactosemia is an autosomal recessive disorder in which a lack of one of the three enzymes involved in the conversion of galactose into glucose causes a rise in serum galactose levels. Galactitol accumulates in the lens fibers, drawing water into them. Infantile anterior and posterior subcapsular opacities progress to become nuclear. Galactose 1-phosphate uridylyltransferase galactosemia is associated with failure to thrive, mental retardation,

and hepatosplenomegaly. Dietary restriction of galactose prevents cataract progression. Galactokinase deficiency is associated with galactosemia and cataract but without the systemic manifestations.<sup>25</sup>

Fabry's disease is an X-linked lysosomal storage disorder that results in accumulation of the glycolipid ceramide trihexoside. The patient suffers from episodic fever, pains, hypertension, renal disease, and a characteristic rash. In the affected man and the carrier woman, a typical mild, spokelike, visually insignificant cataract develops.

Lowe's or oculocerebrorenal syndrome is a severe X-linked disorder that results in mental retardation, renal tubular acidosis, metabolic acidosis, and renal rickets. Congenital glaucoma, cataracts, and corneal keloids can cause blindness. The lens is small and discoid with a total cataract. Female carriers may show focal dot opacities in the cortex.

Alport's syndrome is a dominant, recessive, or X-linked trait disease causing hemorrhagic nephropathy and sensorineural deafness. Congenital or postnatal cortical cataract, anterior or posterior lenticonus, and microspherophakia occur.

Dystrophia myotonica is a dominantly inherited disorder and results in muscle wasting and tonic relaxation of skeletal muscles. Other features include premature baldness, gonadal atrophy, cardiac defects, and mental retardation. Cataract is a key diagnostic criterion and may develop early, but usually occurs after 20 years of age and progresses slowly, eventually becoming opaque. Early cataract consists of polychromatic dots and flakes in the superficial cortex. As the opacities mature, a characteristic stellate opacity appears at the posterior pole. Other ocular features include hypotony, blepharitis, abnormal pupil responses, and pigmentary retinopathy.

Rothmund-Thomson syndrome is an autosomal recessive disorder characterized by poikiloderma, hypogonadism, saddle-shaped nose, abnormal hair growth, and cataracts, which develop between the second and fourth decades of life and progress rapidly.

Werner's syndrome or adult progeria is an autosomal recessive disorder with features that include premature senility, diabetes, hypogonadism, and arrested growth. Juvenile cataracts are common. The condition usually leads to death at about 40 years of age.

Cockayne's syndrome causes dwarfism but with disproportionately long limbs with large hands and feet, deafness, and visual loss from retinal degeneration, optic atrophy, and cataracts.

## Dermatological Disorders

The skin and the lens are of ectodermal origin embryologically. Therefore, skin disorders may be associated with cataract formation.

Atopic dermatitis and eczema may affect any part of the body, especially the limb flexures. Localized proliferation of lens epithelium occurs in some atopic adults, usually as a bilateral, rapidly progressive "shield" cataract (a dense, anterior subcapsular plaque with radiating cortical opacities, and wrinkling of the anterior capsule). Posterior subcapsular opacities also may occur.

Ichthyosis is an autosomal recessive disorder that features hypertrophic nails, atrophic sweat glands, cuneiform cataracts, and nuclear lens opacities.

Incontinentia pigmenti is an X-linked dominant disorder that affects skin, eyes, teeth, hair, nails, and the skeletal, cardiac, and central nervous systems. Blistering skin lesions occur soon after birth, followed by warty outgrowths. Ocular pathology includes cataract, chorioretinal changes, and optic atrophy.

## Central Nervous System Disorders

Neurofibromatosis (types I and II) is an autosomal dominant disorder causing numerous intracranial and intraspinal tumors and acoustic neuromata. Ocular features include combined hamartoma of the retina and retinal pigment epithelium, epiretinal membranes, Lisch nodules (a diagnostic sign), and posterior subcapsular or cortical cataracts that develop in the second or third decade of life.

Zellweger syndrome, also known as hepatocerebrorenal syndrome, is an autosomal recessive disorder characterized by renal cysts, hepatosplenomegaly, and neurological abnormalities. Ocular features include corneal clouding, retinal degeneration, and cataracts.

Norrie's disease is an X-linked recessive disorder that causes leukokoria and congenital infantile blindness and is associated with mental retardation and cochlear deafness. In the eye, vitreoretinal dysplasia, retinal detachment, vitreous hemorrhage, and formation of a white retrolental mass occur. Eventually, a cataract forms.

## Ocular Disease and Cataracts

Inflammatory uveitis (e.g., Fuchs' heterochromic cyclitis and juvenile idiopathic arthritis) usually results in posterior subcapsular or posterior cortical lens opacities. Infective uveitis (e.g., ocular herpes zoster, toxoplasmosis, syphilis, and tuberculosis) can cause cataracts, but the organism does not penetrate the lens. In maternal rubella infection, after 6 weeks of gestation, the virus can penetrate the lens capsule, causing unilateral or bilateral, dense, nuclear opacities at birth, or they may develop several weeks or months later. Corticosteroid treatment can cause cataracts. Retinal pigment degenerations such as retinitis pigmentosa, Usher's syndrome, and gyrate atrophy are associated with cataracts, which are usually posterior subcapsular opacities. Retinal detachment and retinal surgery may cause a posterior subcapsular cataract particularly in association with vitrectomy, silicone oil injection, and tamponade, or an anterior subcapsular form may develop because of metaplasia of the lens epithelium after vitreoretinal surgery. High myopia is associated with posterior cortical, subcapsular, and nuclear cataracts. Ciliary body tumors may be associated with cortical or lamellar cataract in the affected quadrant. Anterior segment ischemia may cause a subcapsular or nuclear cataract, which progresses rapidly.

### Toxic Causes

Topical, inhaled, and systemically administered corticosteroids can cause posterior subcapsular cataracts. Direct mechanisms included interaction of corticosteroids with enzymes that affects their function, e.g., corticosteroid modulation of  $\text{Na}^+, \text{K}^+$ -ATPase may cause sodium-potassium pump inhibition affecting osmotic regulation. Corticosteroids also induce crystallin conformational changes, causing aggregation and affect intracellular  $\text{Ca}^{2+}$  homeostasis, causing protein bonding. Indirectly, corticosteroids affect DNA/RNA synthesis of proteins and enzymes, causing metabolic changes, and also may affect ciliary body growth hormone levels responsible for lens cellular differentiation, causing posterior subcapsular opacities.<sup>26</sup>

Chronic use of long-acting anticholinesterases previously used in the treatment of chronic open-angle glaucoma may cause anterior subcapsular vacuoles and posterior subcapsular and nuclear cataracts. Pilocarpine, a shorter acting agent, causes less marked changes. The mechanism of action is unknown. Phenothiazines, such as chlorpromazine, may cause deposition of fine, yellow-brown granules under the anterior capsule in the pupillary zone and may develop into large stellate opacities but are not usually visually significant. The development of the opacities may be related to the cumulative dose of the medication, and photosensitization of the lens may play a role. Allopurinol used in the treatment of gout is associated with cataracts. Psoralen-UV-A therapy for psoriasis and vitiligo has been shown to cause cataracts in very high doses in animal studies but is rare in humans; concomitant UV exposure may be a risk factor. Antimitotic drugs used in the treatment of chronic myeloid leukemia, such as busulfan, may cause posterior subcapsular cataract. The antimalarial chloroquine (but not hydroxychloroquine), which is also used in the treatment of arthritis, may cause white, flake-like posterior subcapsular lens opacities. Amiodarone is used to treat cardiac arrhythmias and causes insignificant anterior subcapsular opacities and corneal deposits. The relationship between statins and cataracts is still controversial.

Siderosis, from a ferrous intraocular foreign body, causes iron deposits in the lens epithelium and iris and results in a brown discoloration of the iris and a flower-shaped cataract. Wilson's disease, an autosomal recessive disorder of copper metabolism, causes a brown ring of copper deposition in Descemet's membrane and the lens capsule, resulting in a sunflower cataract—an anterior and posterior capsular disc-shaped polychromatic opacity in the pupillary zone with petal-like spokes that is not usually visually significant. Hypocalcemia in hypoparathyroidism is associated with cataracts. In children, the cataract is lamellar; in adults it produces an anterior or posterior punctate subcapsular opacity.

### Congenital and Juvenile Cataracts

Congenital cataracts are noted at birth, infantile cataracts occur in the first year, and juvenile cataracts develop during the first 12 years of life. Hereditary cataracts may be associated with other systemic syndromes, such as dystrophia myotonica. About one-third of all congenital cataracts are hereditary and unassociated with any other metabolic or systemic disorders.

Trisomy 21, or Down syndrome, is the most common autosomal trisomy, with an incidence of 1 per 800 births. Systemic features include mental retardation, stunted growth, mongoloid facies, and congenital heart defects. Ocular features include visually disabling lens opacities in 15% of

cases, narrow and slanted palpebral fissures, blepharitis, strabismus, nystagmus, light-colored and spotted irides (Brushfield spots), keratoconus, and myopia. Cataract also is associated with trisomy 13 (Patau's syndrome), trisomy 18 (Edwards' syndrome), Cri du chat syndrome (deletion of short arm of chromosome 5), and Turner's syndrome (X chromosome deletion).

A total cataract is a complete opacity present at birth. It may be hereditary (autosomal dominant or recessive) or associated with systemic disorders such as galactosemia, rubella, and Lowe's syndrome. Infantile cataracts cause amblyopia if unilateral and may cause strabismus and nystagmus if bilateral. The incidence is about 0.4% of newborns, but the majority of cases are not associated with poor vision. Amblyopia depends on the size, location, and density of the cataract. The causes of infantile cataracts are many and include maternal infections (such as rubella), systemic diseases, hereditary disorders, and ocular disease.

## PREVENTION OF CATARACTS

The roles and mechanisms of action of dietary antioxidant vitamins and minerals in the biochemistry and metabolism of the lens are not clear. Ascorbate is a water-soluble antioxidant. Vitamin E is a lipid-soluble antioxidant that inhibits lipid peroxidation, stabilizes cell membranes, and enhances glutathione recycling. Beta-carotene, the best-known carotenoid, is a lipid-soluble antioxidant and a vitamin A precursor and is one of 400 naturally occurring carotenoids. There are mixed reports in the literature with some studies showing no benefit and others showing some benefit with vitamin A, carotenoids, and combinations of vitamins C and E and beta-carotene supplements.<sup>27,28</sup>

Potential anticataract compounds include aldose reductase inhibitors, pantethine, and aspirin-like drugs such as ibuprofen. However, none of these agents has been shown to prevent cataracts in a trial setting. No convincing evidence exists that N-acetylcarnosine reverses cataract or prevents progression of cataract. A decreased risk of developing cataracts occurs with estrogen replacement therapy.<sup>29-34</sup> New drugs are under investigation, including lanosterol, which decreased protein aggregates in vitro, reduced cataract severity, and increase transparency in rabbit cataractous lenses in vitro and cataract severity in vivo in dogs.<sup>35</sup> Anticataract agents would need to be safe for long-term use and sufficiently inexpensive to compete with increasingly cost-effective cataract surgery.

Understanding the causes of age-related cataract will be helpful in preventing or delaying cataract formation, but our knowledge is incomplete. Minor risk factors such as UV-B exposure and smoking can be modified but are not likely to result in large reductions in visual disability. The most important risk factor, aging, cannot be modified. Other strategies such as nutritional, pharmacological, and specific medical and genetic interventions may be helpful in the future but are of unproved benefit at present. Integrated and innovative approaches to the provision of surgery, resource management, training, start-up capital equipment and consumables, and cost-recovery mechanisms are required.

## MORPHOLOGY AND VISUAL EFFECTS OF CATARACT

### MORPHOLOGY

Nuclear opacities are caused by a gradual increase in the optical density of the central nucleus, progressing slowly to involve more superficial layers (see Fig. 5.3.1). The nucleus may change color from clear to yellow to dark brown.

Cortical opacities are spokelike peripheral opacities that reduce the visual acuity as they extend toward the visual axis (see Fig. 5.3.2).

Posterior subcapsular opacities begin at the posterior polar region then spread toward the periphery. Patients have significant glare disability because of light scattering at the nodal point of the eye.

Complete opacification of the lens eventually occurs, usually with combinations of the different forms. The crystalline lens may swell to form an intumescent cataract. The cortical material may then liquefy and be absorbed causing the solid nucleus to "sink" to the bottom of the capsular bag.

## ASSESSMENT AND GRADING OF CATARACTS

Grading and classifications of cataracts (Box 5.3.1) are useful in research, to explore causation, and in trials of anticataract drugs. Slit-lamp direct and

**Fig. 5.3.4 Cataracta Centralis Pulverulenta.** Opacification of fetal nucleus.

### BOX 5.3.1 Infantile Cataracts

#### Anterior Polar Cataract

Dominantly inherited, well-defined opacities of the anterior capsule may affect the vision.

Caused by imperfect separation of lens from surface ectoderm, by epithelial damage, or by incomplete reabsorption of the vascular tunic of the lens.

May have anterior or posterior conical projections; if it extends into the cortex in a rod shape, it is called a “fusiform” cataract.

#### Spearg Cataract

Dominantly inherited, polymorphic cataract with needle-like clusters of opacities in the axial region, which may not affect vision.

#### Coralliform Cataract

Dominantly inherited cataract that consists of round and oblong opacities grouped toward the center of the lens; they resemble coral.

#### Floriform Cataract

A rare, ring-shaped, bluish white, flower-shaped cataract in the axial region.

#### Lamellar Cataract

A common, bilateral, and symmetrical round, gray shell of opacity that surrounds a clear nucleus; usually dominantly inherited cataract, which may have a metabolic or inflammatory cause.

Fibers become opacified in response to a specific insult during their most active metabolic stage and are pushed deeper into the cortex as normal lens fibers are laid down around it.

#### Cataracta Centralis Pulverulenta

Dominantly inherited, nonprogressive cataract consisting of fine, white, powdery dots within the embryonic or fetal nucleus (Fig. 5.3.4).

#### Congenital Punctate Cerulean Cataract

Bilateral, nonprogressive, small, bluish dots scattered throughout the lens with little effect on vision.

#### Congenital Suture (Stellate) Cataract

Dominantly inherited bluish dots or a dense, chalky band around the sutures affecting one or both fetal sutures, especially posteriorly; may interfere with vision.

#### Mittendorf's Dot

A small (about 1 mm diameter), nonprogressive, white condensation occurs on the posterior pole of the lens capsule; it may be decentered slightly inferonasally and may be attached to a free-floating thread in the vitreous gel, which represents the anterior part of the hyaloid artery remnant.

#### Congenital Disciform Cataract

Central thinning creates a doughnut shape, which may arise from failure of development of the embryonic nucleus.

retroillumination of nuclear, cortical, and posterior subcapsular cataracts is used in the Lens Opacification Classification System II (LOCS-II). LOCS-II is reproducible and has been validated.<sup>36</sup> A number of Scheimpflug camera and optical coherence tomography devices have been developed for objectively quantifying lens opacification.

## VISUAL EFFECTS OF CATARACTS

The effect of cataract on vision varies according to the degree of the cataract and the cataract morphology.

### Visual Acuity

Reduction in visual acuity has been the standard measure of the visual effect of cataracts. However, visual acuity can remain good despite other cataract-related effects on vision that compromise the patient's ability to function.

### Contrast Sensitivity, Glare, and Wavefront Aberrometry

Cataracts cause reduced contrast sensitivity and increased wavefront aberrations, reducing visual acuity especially at low ambient light levels.<sup>37</sup> Glare, which occurs as a result of forward scatter of light, may be produced by opacities that do not lie within the pupil diameter and, therefore, affect visual function.<sup>38</sup>

### Other Effects

The natural aging of the human lens produces a progressive hyperopic shift. Nuclear changes induce a modification of the refractive index of the lens and produce a myopic shift. Cortical opacities may cause localized changes in the refractive index of the lens, which may result in monocular diplopia. Color perception is affected by the yellowing of the lens nucleus. The morphology, density, and location of lens opacities may cause changes in the visual field.

## ANOMALIES OF LENS GROWTH

The lens is ectodermal and the vascular capsule is mesodermal in origin. A number of exogenous or endogenous influences can affect ectodermal or mesodermal development and can have multiple manifestations in the eye.

### Aphakia

Aphakia is the absence of the lens. Primary aphakia is a rare absence of the lens. Secondary aphakia is more common, and there are lens remnants. Both occur in isolation or with other abnormalities of the anterior segment such as microphthalmos, microcornea, and nystagmus.<sup>39</sup>

### Microspherophakia

Microspherophakia is the presence of a small, spherical crystalline lens with an increased antero-posterior thickness and steeper than normal anterior and posterior lens curvatures. It is bilateral and may be familial, may occur as an isolated defect, or may be associated with other mesodermal defects, such as the Weill–Marchesani and Marfan's syndromes. The condition causes lenticular myopia and may be associated with lens dislocation (usually downward) and pupil block.<sup>40,41</sup>

### Lenticonus and Lentiglobus

Abnormalities of the central lens curvature include lenticonus (conical) and lentiglobus (spherical) and may be anterior or posterior. They may be associated with abnormalities of the lens epithelium, by traction from hyaloid remnants, or by localized areas of capsule weakness, which causes bulging. They may be inherited as an autosomal recessive trait or associated with other abnormalities, such as Alport's syndrome (familial hemorrhagic nephritis) or Lowe's oculocerebral syndrome (associated with posterior lenticonus). They can cause lenticular myopia with irregular astigmatism.<sup>39,41</sup>

**Fig. 5.3.5 Marfan's Syndrome.** A retroillumination slit-lamp photograph of ectopia lentis associated with Marfan's syndrome.

## Lens Coloboma

Lens coloboma is a unilateral, congenital indentation of the lens periphery that occurs as a result of a localized absence of zonules. It may be associated with coloboma of the iris, ciliary body, or choroid, or with ectopia lentis, spherophakia, or localized lens opacities. It may occur because persistence of mesodermal vascular capsules remnants prevents the development of zonules in that area.

## Ectopia Lentis

Ectopia lentis, or displaced lens, is usually a bilateral condition caused by extensive zonular malformation. The lens is subluxated in the opposite direction to the weak zonules (usually superomedially) and usually

presents in childhood or young adulthood. The lens may dislocate completely into the anterior chamber or vitreous or become cataractous. It may be an autosomal dominant or recessive trait or may be associated with other developmental abnormalities of the eyes such as iris coloboma, microspherophakia, aniridia, and ectopia pupillae congenita. It may be associated with systemic disorders such as Marfan's syndrome (Fig. 5.3.5), Weill–Marchesani syndrome, homocystinuria, sulfite oxidase deficiency, and hyperlysinemia. The clinical features of a subluxed lens include iridodonesis (tremulous iris), fluctuating anterior chamber depth and vision, and phacodonesis (a visibly mobile lens). Vitreous may herniate into the anterior chamber. Pupil block may occur with iris apposition to the vitreous face or an anterior dislocated lens (into the anterior chamber).

# Patient Workup for Cataract Surgery

Frank W. Howes

## 5.4

**Definition:** Preoperative preparation prior to planned lens extraction.

### Key Features

Ophthalmic and medical considerations in the preoperative evaluation of lens surgery include:

- The morphology of lens opacities and the effects and diagnosis thereof.
- The optics of the eye, including refractive correction modalities.
- The biometric measurements in standard and nonstandard eyes.
- The optimal medical assessment of the patient for surgery.
- The social and legal considerations in final aspects of the workup are discussed.

### INTRODUCTION

Any patient undergoing cataract surgery requires an accurate ophthalmological workup and careful anamnesis. Although most cataract procedures are uneventful with regard to the patient's medical condition, any problem or crisis is potentially ruinous, especially if surgery becomes complicated or prolonged. Therefore it is incumbent on the surgical, anesthetic, nursing, and family doctor teams to be fully aware of their patient's surgical and medical status.

### MEDICAL HISTORY AND CURRENT THERAPEUTIC REGIMEN

A history of cardiac, bronchopulmonary, or cerebrovascular incidents influences the timing and management of surgery, especially if it is recent. Diabetes mellitus and systemic hypertension are common in the population predisposed to operable cataract formation, and these conditions may adversely influence both the surgery and the postoperative course of events.<sup>1</sup> Ram and coworkers<sup>2</sup> carried out a study of more than 6000 patients who underwent cataract surgery and discovered multiple morbidities that arose from a variety of conditions. The major causes included pulmonary disease, cardiovascular and hypertensive disorders, diabetes mellitus, and significant orodental problems that required intervention.

Ram et al.<sup>2</sup> also noted significant postoperative problems in 1.27% of their patients, nearly half of whom required hospitalization. Fisher and Cunningham<sup>3</sup> and Hamed et al.<sup>4</sup> noted an even higher morbidity in their cohort of patients who had cataract surgery (Table 5.4.1).

There are many factors that may affect cooperation and difficulty during surgery, varying from ventilation difficulties to substance abuse (including examination of identified cataract morphological findings), that may influence both the surgeon's and the anesthesiologist's decision about the form

of anesthetic to use and the sedation required and potentially both the pre- and postoperative management (Table 5.4.1 and 5.4.2).

### GENERAL OPHTHALMIC HISTORY AND EXAMINATION

Both eyes are assessed fully by routine ophthalmological workup, which includes tonometry, slit-lamp biomicroscope examination, and posterior segment observations under mydriasis to estimate the visual outcome and risk category of surgery for the patient. Intercurrent ophthalmic disorders may prejudice the visual outcome. For example, uveitis may be exacerbated,<sup>5</sup> herpes zoster may have left an anesthetic cornea,<sup>6</sup> atopic disease may predispose the eye to infection,<sup>7</sup> and Fuchs' endothelial dystrophy may predispose the eye to corneal edema. Diabetes mellitus increases the prospects of postoperative macular edema.<sup>1</sup>

The presence of open-angle glaucoma warrants further comment. The aforementioned disease processes need pickup and assessment to avoid deleterious effect on the eye after cataract surgery. The action of successful cataract surgery on glaucoma and ocular hypertension, however, has been demonstrated to have a positive effect on intraocular pressure (IOP) control.<sup>8</sup>

With the advent of the new minimally invasive glaucoma surgery (MIGS) procedures, the surgeon should now consider using one of these devices at the end (or beginning) of a cataract procedure to further facilitate improved aqueous outflow, lower IOP,<sup>9-11</sup> and improve glaucoma control, potentially reducing or eliminating the use of topical glaucoma drugs, which themselves can have an adverse influence on the ocular surface and visual quality both before and after cataract surgery. There are a number of MIGS devices available; see a commonly used example at Fig. 5.4.1.

Patient counseling on the procedure and explanation of postoperative expectation are vital elements of the preoperative workup. A written explanation of the background and process of cataract surgery is invaluable.

### ASSESSMENT OF LENS OPACITIES<sup>12,13</sup>

#### INTRODUCTION

The progressive insolubilization of lens protein with age is believed to cause refractive index and density fluctuations, which scatter light and impair vision.

TABLE 5.4.2 Systemic Disorders and Lens Opacities

Systemic Disorder	Appearance in the Eye
Myotonic dystrophy	Blue dot cortical cataract and posterior subcapsular cataract
Wilson's disease	Green sunflower cataract (copper) anterior or posterior subcapsular
Atopic dermatitis	Blue dot cortical cataract and posterior subcapsular cataract
Hypocalcemia	Discrete white cortical opacities
Diabetes mellitus	Snowflake opacities located in anterior and posterior subcapsular cortex
Acute onset diabetes	Cortical wedges caused by lens fiber swelling
Down syndrome	Snowflake opacities located in anterior and posterior subcapsular cortex
Systemic conditions requiring corticosteroids (any form of administration)	Posterior subcapsular lens opacities

TABLE 5.4.1 Morbidity in Cataract Surgery Patients

Condition	Percentage
Significant medical history	84
Diabetes mellitus	16
Systemic hypertension	47
Ischemic heart disease	38
Hypothyroidism	18
Undiagnosed tumors	3

**Fig. 5.4.1** Glaukos version 1 iStent (G1) (A) and version 2 iStent inject (G2) (B) Trabecular microbypass system (MIGS). (Image used with permission from Glaukos Inc.)

The impact of a patient's cataract on the retinal image may be appreciated on funduscopic examination, which can show interference with the red reflex and show the blur of fine retinal vessels.

## DIAGNOSIS OF LENS OPACITIES

Slit-lamp biomicroscopy is the major method used to observe and assess cataracts. However, the image seen often fails to correlate with the patient's visual acuity or function. The relationship between alterations in the structural proteins, the increase in light scatter associated with conventional biomicroscopy, and the capacity of visual function is not a simple one. For all lens examinations, the pupil is dilated maximally.

## CLASSIFICATION OF LENS OPACITIES

### Nuclear Opacities

Initially, an increase in optical density of the nucleus occurs (nuclear sclerosis). The fetal nucleus is first involved and then the whole adult nucleus. The increase in density is followed by an opacification, which implies a change in color, namely from an initial clear to yellow to a subsequent brown (brunescient cataract).

In certain instances, crystals appear in the adult nucleus (or in the cortex, usually posteriorly) that, on slit-lamp examination, appear to be of different colors (polychromatic luster).

### Cortical Opacities

The changes in transparency involve most of the cortex of the lens. The changes evolve as follows:

- Hydration of the cortex with development of subcapsular vacuoles.
- Formation of ray-like spaces filled with liquid (morgagnian globules), which is at first transparent and later becomes opaque.
- Lamellar separation of the cortex with development of parallel linear opacities.
- Formation of cuneiform opacities that originate at the periphery of the lens and spread toward the center.

## Posterior Subcapsular Opacities

Posterior subcapsular opacities may develop as isolated entities or may be associated with other lens opacities. The opacity begins at the posterior polar region and then spreads toward the periphery. Often, granules and vacuoles are detectable in front of the posterior capsule.

## Advanced Cataracts

The crystalline lens may swell and increase in volume because of cortical processes (intumescent cataract). Complete white opacification of the lens is called a mature or morgagnian cataract.

If the liquefied cortical material is not—or is only partially—reabsorbed, the solid nucleus may “sink” to the bottom. Reabsorption of the milky cortex causes a reduction in the lens volume, resulting in capsular folding (hypermaturation cataract).

## GRADING OF LENS OPACITIES

Gradations and classifications of cataracts are useful in determining the potential difficulty of cataract surgery, in cataract research, in studies to explore causation, and in trials of putative anticataract drugs. Devices designed to quantify lens opacification have been developed<sup>14</sup>; these instruments (such as the Kowa Early Cataract Detector and the Scheimpflug photo slit lamp) appear to be more accurate when used to assess the formation of nuclear cataracts than that of cortical cataracts.

A rapid method for the gradation of cataract in epidemiological studies has been reported by Mehra and Minassian<sup>15</sup>; the area of lenticular opacity is assessed by direct ophthalmoscopy and graded on a scale from 0 to 5. Highly reproducible, validated systems (Lens Opacities Classification System III; see next section) for cataract classification have been developed by Chylack and coworkers<sup>16</sup> to define the effects of specific cataract type and extent very accurately; these enable the effects of specific cataract types on specific visual functions to be quantified.

## Lens Opacities Classification System III

(Fig. 5.4.2)

For nuclear opalescence (NO) or nuclear color (NC), a slit beam is focused on the lens nucleus and the density of the lens is compared with a set of standard photographs. If the density is less than that corresponding to the first photograph, NO or NC is zero or “no nuclear cataract”; if NO or NC is 1, the density is equal to or less than that for the second photograph, and so on. The photographs represent lens nuclei of increasing density, and the patient's cataract is graded accordingly.

For cortical cataracts (category “C”), a retroillumination (red reflex) view through the dilated pupil is used to view the lens, focused first at the anterior capsule and then at the posterior capsule. The photographs are compared with standard photographs—each succeeding photograph shows the pupillary area covered by more cortical cataract.

For posterior subcapsular cataract (category “P”), a retroillumination (also red reflex) view of the lens is used, focused at the posterior capsule. Again, the patient's cataract is graded according to standard photographs (see Fig. 5.4.2).

## EFFECTS OF OPACITIES ON VISION

### Visual Acuity Reduction

Measurement of visual acuity can remain high despite age-related lens opacities.<sup>17–18</sup> The severity of the visual disability measured using high-contrast Snellen acuity charts is not sensitive to visual disability characterized by loss of contrast sensitivity.

Usually, visual acuity testing is conducted under ideal circumstances that are not normally met in the real world. Although not a definitive measurement of visual dysfunction, simple Snellen acuity is the most used index to determine whether cataract surgery should be performed. The Preferred Practice Pattern of the American Academy of Ophthalmology recommends Snellen acuity as the best general guide to the appropriateness of surgery but recognizes the need for flexibility with due regard to a patient's particular functional and visual needs, environment, and risks, which may vary widely.<sup>19</sup>

When the cataract is very dense and opaque, visual acuity may be reduced to light perception only (cataract is still the major cause of blindness throughout the world).

**Fig. 5.4.2** Lens Opacities Classification System III Simulation Chart.

## Contrast Sensitivity Reduction

Patients with cataracts commonly complain of loss of the ability to see objects outdoors in bright sunlight and of being blinded easily by approaching headlamps in nighttime driving.<sup>20</sup>

Typically, loss of contrast sensitivity in patients who have cataracts has been reported to be greater at higher spatial frequencies. All cataracts lower contrast sensitivity—the posterior subcapsular opacities have been reported to be the most destructive.

## Myopic Shift

The natural aging of the human lens produces a progressive hyperopic shift. Nuclear changes induce a modification of the refractive index of the lens and produce a myopic shift that may be of several diopters or greater. It is possible to predict that an aging person who had emmetropia previously but who can now read with no correction (“second sight”) is developing nuclear cataract. Together with this aging effect goes the loss of the negative asphericity of the lens in youth, balancing the positive asphericity of the natural cornea.<sup>21</sup> The shift to more positive asphericity of the lens with progressive nuclear cataract also reduces visual quality.

If the lens structure becomes heterogeneous, with cortical spoke cataract for example, the change in refractive index may be uneven and may produce some degree of internal irregular astigmatism and disturbance of the higher-order aberrations of Zernike (third order).

## Monocular Diplopia

Monocular diplopia is common in patients who have lens opacities, particularly cortical spoke cataract, and in conjunction with water clefts that form radial wedge shapes and contain a fluid of lower refractive index than the surrounding lens. In some cases, patients may complain of polyopia.

## Glare

Even minor degrees of lens opacity cause glare because of the forward scatter of light.<sup>22</sup> Such patients often see more poorly in daylight conditions than in the context of night driving. Unlike contrast sensitivity reduction, some glare may be produced by opacities that do not lie within the pupil diameter. The differences between measured visual acuity in a darkened room and acuity in ambient light that produces glare are useful as subjective criteria for the justification of surgery.

## Color Shift

The cataractous lens becomes more absorbent at the blue end of the spectrum, especially with nuclear opacities. Usually patients are not aware of this color visual defect until after cataract surgery and visual rehabilitation.

## Visual Field Loss

According to the morphology, the density, and the location of the opacities, the field of vision may be affected.

## INVESTIGATIONS FOR FURTHER SURGICAL REFINEMENT

### CORNEAL TOPOGRAPHY<sup>23</sup>

The use of corneal topography<sup>24</sup> is facilitatory in the fulfillment of current expectations of outcomes of surgery of within 0.5 diopters (D) of emmetropia, with minimal astigmatism.

### PREOPERATIVE TOPOGRAPHY

The preoperative assessment of corneal topography has a number of roles in cataract surgery. First, as an alternative to keratometry, it can provide a representative measure of the corneal curvature or power necessary to calculate intraocular lens (IOL) power. Second, knowledge of the magnitude and location of pre-existing astigmatism is important if it is to be reversed by appropriate placement and construction of incisions during surgery. Furthermore, with the advent of toric IOLs, the decision whether to use this technology is based on the topographic or keratometric measurement of corneal astigmatism. Variations in the measurement of corneal astigmatism are often seen from instrument to instrument with the inherent danger of mal-powering or mal-placing the toric IOL, hence the need to perform more than one form of keratometric assessment.

Modern topographic devices are now capable of measuring higher-order aberrations (Zernike), which can further help with optimizing surgical outcomes. The second and third order aberrations of Zernike may be reduced by removal of the cataract and by accurate biometric measurements. The fourth order aberration, in particular spherical aberration, which changes with age,<sup>21</sup> can be modified by IOL choice (differing spherical aberration values) to provide better acuity or greater depth of focus.<sup>25</sup>

### DETERMINATION OF IOL TYPE AND POWER

Prior to cataract surgery, the power of the IOL that is required to give the desired postoperative refraction is determined. The final refractive result is dependent on the accuracy of the biometric data and its appropriate use in relevant calculations.

Achieving emmetropia (or the desired refractive outcome) by optimal biometric assessment is the most important aspect of the workup for cataract surgery. With the advent of the new extended range of focus IOLs now available on the market, the default position of the standard monofocal

IOL is being challenged. The surgeon is now potentially in the position where he or she should discuss in detail with his patient why he or she should not have one of these new lenses. The scope of the art of surgery has widened since the introduction of these lenses.

The factors under consideration for the surgeon are therefore:

- Is the patient ready for surgery (risk–benefit analysis)?
- If so, what is the scope of the workup required as calculated against the patient's medical and ophthalmological status?
- What are the patient's optical needs and what technologies are required to fulfill expectations?
- What workup is required to enhance the accuracy of outcome for those needs?
- What is the surgeons' expectation in terms of his or her capability of providing the match for the patient's expectation?
- And finally, have all the above been conveyed in an understandable manner to the patient?

## PLANNING THE INCISION

The final part of the patient workup for cataract surgery is planning the incision. This involves making the decision on the optimal corneal position of the operative incision in relation to the surgical accessibility (nose, operating table, side, etc.) for efficient execution of the surgery and whether the operative incision should be the same as the therapeutic incision for the management of the corneal astigmatism. The effect of the incision on astigmatism is modifiable by the axis location of the incision, the length of the incision, and the proximity to the visual axis (scleral, limbal, or corneal).

The incision-making process also is modified by the decision about whether to use the toric IOL technology. The factors used in this decision-making process relate to the degree of astigmatic refractive error, IOL availability, outcome target, and keratometric and topographic measurements. Technology improvements have permitted the importation of keratometric data from the workup room to the operating theater. Manufacturers have created imaging systems within microscopes that recognize and track the eyes being operated on and provide overlay information through the microscope oculars to demonstrate exactly where corneal incisions should be placed and on what axis a toric IOL should be positioned. Capabilities even extend to overlays for particular capsulorrhexis size and IOL centration.

## GOOD CLINICAL PRACTICE (SOCIAL AND LEGAL ASPECTS)

The indications for surgery vary from patient to patient, especially with the current minimally invasive nature of cataract and lens implant surgery (compared with such surgery performed only a few years ago). The visual needs of patients vary according to their ages, occupations, and leisure interests. A cataract may not be symptomatic. Visual symptoms and outcome expectation affect the risk–benefit ratio.

Although the risks of technically well-performed small incision surgery are few in a healthy eye, patients require enough information on which to base their decision to proceed. Most patients are inclined to accept the professional judgment of the ophthalmic surgeon, but it is implicit that an adult of sound mind has the right to determine whether surgery should proceed. Therefore, in the context of cataract surgery, how much information is it necessary for an ophthalmologist to disclose to a patient? To what extent should an ophthalmologist shield a patient from the anxieties that can accompany a full explanation of diagnosis and treatment?

An ophthalmologist must strike a balance between providing enough information to enable the patient to give informed consent with respect to treatment and engendering the confidence and trust that encompasses a joint decision to proceed. The surgeon shoulders the major responsibility for this, which should be accepted as a consequence of medical and specialist training.

In the application of professional judgment, the consideration of alternative management strategies, risks, and benefits allows a patient to make some sort of informed evaluation of the options. Statistical information based on published data may be confusing: Where does the patient fit into the statistics? What are the personal outcome statistics for the surgeon who offers advice? What guarantees are there that a particular surgeon will perform the surgery?

A problem arises if potential material risks and dangers are not disclosed to a patient before surgery and a complication occurs. The patient may claim that, with prior knowledge of such a risk, he or she would not have consented to the surgery. A risk is material when a rational patient considers the risk of undergoing a certain type of treatment to be significant.

Problems that arise from consent to perform surgical procedures can be minimized but not completely avoided, because every contingency cannot be reviewed completely. Taking the following steps will ensure that a thorough approach has been used.

Appropriate patient education is required—the procedure is described in a manner that allows the patient to appreciate what will be done to treat the eye. Although the decision to proceed has to be the patient's, the surgeon must not pass all the responsibility on to the patient; instead the surgeon should communicate the appropriate degree of confidence in the procedure's outcome.

The surgeon has to assume much of the responsibility for treatment advice, because the patient cannot appreciate the intricacies of every surgical situation. Ultimately, the patient has to have faith in the ability of the surgeon not only to carry out the procedure but also to make the judgment that the benefits far outweigh the risks. An analogous situation might be that of a passenger contemplating a journey on a commercial airliner. If the passenger inquires of the pilot what the potential risks are, common sense suggests that the answer would be that they are high in number but low in expectation. A passenger who decides to make the trip has confidence in the airline and the crew to complete a successful journey. So it is with surgery: The patient must have confidence in the ability of the surgeon and the surgical team to carry out a successful procedure without knowing each and every pitfall that exists.

Alternative approaches to the management of an ophthalmic condition are explained to the patient to enable patient participation in the final direction of treatment.

When uncertainties exist, the patient is advised of the predictability of the planned procedure, its stability, and its safety. Statistical information on outcome is of limited value when given in a general sense. Few surgeons are in a position to give specific statistical information about the outcome of their own practices or of certain procedures.

The patient must be given adequate time to decide. At the end of the consultation, a patient must have an opportunity to consider the treatment that has been advised or to reverse a decision to proceed. It is inappropriate to obtain a patient's signed consent for a procedure and then proceed at very short notice (the same day) with that treatment. The delay between consent and treatment must be sufficient to allow the patient to consider the matter fully.

To ensure that a patient is fully informed with regard to consent for a surgical procedure, the issues listed in [Box 5.4.1](#) should be covered.

The patient should sign a consent form that states that the procedure has been explained fully in language that is comprehensible and that there has been sufficient opportunity to ask questions and reconsider consent prior to surgery. A written guide helps patients comprehend the nature of the planned surgery.

Any surgical intervention is essentially a matter of trust and confidence—the trust of the patient in the surgeon's ability and integrity and the trust of the surgeon in the patient's ability to comprehend and follow the process and to comply with prescriptions for managing the condition before, during, and after surgery.

### BOX 5.4.1 Issues to Discuss With a Patient Prior to Cataract Surgery

- The purpose of the surgery
- The surgical procedure
- The anesthetic requirements
- Commonly experienced visual conditions after the surgery, even if temporary
- That temporary postsurgical visual conditions may become permanent under certain conditions
- The serious complications that may follow surgery
- Potential pain or ocular discomfort
- The refractive requirements after the surgery (the need to wear and the provision of spectacles and/or contact lenses)
- The potential need for additional procedures (planned staged procedures)
- Alternative management of the condition

# Intraocular Lens Power Calculations

Li Wang, Kourtney Houser, Douglas D. Koch

# 5.5

**Definition:** Intraocular lens (IOL) power calculation is a process to determine the optimal IOL power to achieve the desired refraction following cataract surgery.

### Key Features

- Accurate IOL power calculation depends on the precision of the preoperative biometric data and the accuracy of the IOL formulas.
- New biometers using interferometry and swept-source OCT have improved accuracy and expanded the number of biometric parameters that can be measured.
- IOL power calculation is less accurate in special eyes, including short eyes, eyes with ectatic corneas, or eyes that have undergone corneal refractive surgery or keratoplasty. The American Society of Cataract and Refractive Surgery (ASCRS) postrefractive IOL calculator is a useful tool.
- When selecting the toricity of the toric IOL, several factors must be taken into account. Imaging and guidance systems for toric IOL alignment have been developed.

### INTRODUCTION

Accurate intraocular lens (IOL) power calculation is a crucial element for meeting the ever-increasing expectations of patients undergoing cataract surgery. Despite advances in technology and IOL calculation formulas, much is yet to be done. The accuracy of IOL power calculations depends on the precision of the preoperative biometric data, the accuracy of the IOL formulas, and the IOL quality control by the manufacturer.

In this chapter, we will discuss (1) ocular biometry; (2) IOL power formulas; (3) IOL power calculations in special eyes, including short eyes, long eyes, and eyes with previous corneal refractive surgery; (4) toric IOL selection; (5) intraoperative wavefront aberrometry; and (6) postoperative IOL adjustment.

### OCULAR BIOMETRY

Accurate biometry is of vital importance in achieving a predictable postoperative refraction following cataract surgery. Norrby<sup>1</sup> analyzed the sources of error in IOL power calculation by analyzing the precision of the biometric and clinical measurements. He concluded that the three greatest sources of error were axial length (AL), effective lens position (ELP), and postoperative refraction, contributing 79% of the total error.

### Ultrasound Biometry

AL has traditionally been measured using ultrasound biometry. With the applanation technique, the ultrasound probe is placed in direct contact with the cornea, and corneal compression typically causes the AL to be falsely shortened. Applanation biometry has given way to noncontact methods. Although the immersion technique has been shown to be more reproducible than the applanation technique, both require mindfulness of the properties of ultrasound. In eyes with high to extreme axial myopia, the presence of a posterior staphyloma should be considered. Erroneously long AL readings may occur in eyes with staphylomata. An immersion A/B-scan approach for AL measurement has been described in the setting of posterior staphyloma.<sup>2</sup>

With A-scan biometry, errors in AL measurement account for 54% of IOL power error when two-variable formulas are used.<sup>3</sup>

### Optical Biometry

Optical biometry has been shown to be significantly more accurate and reproducible and is rapidly becoming the most prevalent methodology for the measurement of AL. The most commonly used optical biometers are IOLMaster (Carl Zeiss Meditec, Jena, Germany) and Lenstar (Haag-Streit, Koeniz, Switzerland).

- **IOLMaster:** The IOLMaster 500 was introduced in 2000 as the first optical biometer. Based on partial coherence interferometry technology, it uses a 780-nm laser diode to measure AL. The device also provides measurements of keratometry, anterior chamber depth (ACD), and white-to-white (WTW) distance.

The newer version of this device (IOLMaster 700) uses an optical configuration that allows telecentric and thus distance-independent keratometry measurement. It uses swept-source optical coherence tomography (OCT) to measure axial length, central corneal thickness (CCT), and lens thickness (LT). It displays a full-length OCT image, showing anatomical details of a longitudinal cuts through the entire eye (Fig. 5.5.1).

- **Lenstar:** Based on optical low-coherence reflectometry technology, the Lenstar uses an 820-nm laser diode to measure AL, ACD, CCT, and LT. It calculates keratometry from an array of 32 light reflections projected off the anterior corneal surface.
- **Argos (Movu Inc, Komaki, Japan) and OA-2000 (Tomey, Nagoya, Japan):** These are two other new swept-source biometers that recently been introduced.

Studies<sup>4-6</sup> have shown that the repeatability of the IOLMaster and Lenstar for all biometric parameter measurements is excellent and that agreement between these devices is good. The differences in AL, ACD, and LT between these devices were not shown to produce a statistically significant difference in IOL power calculation.

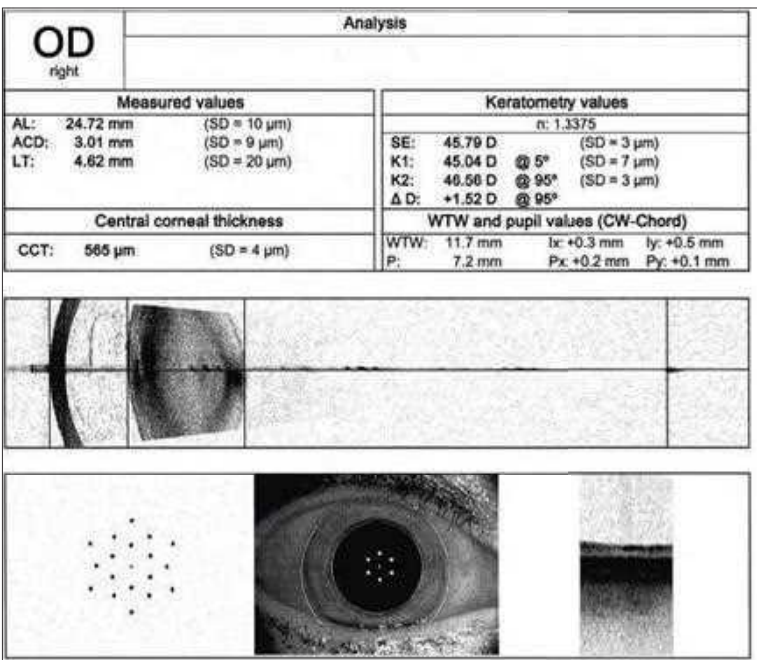

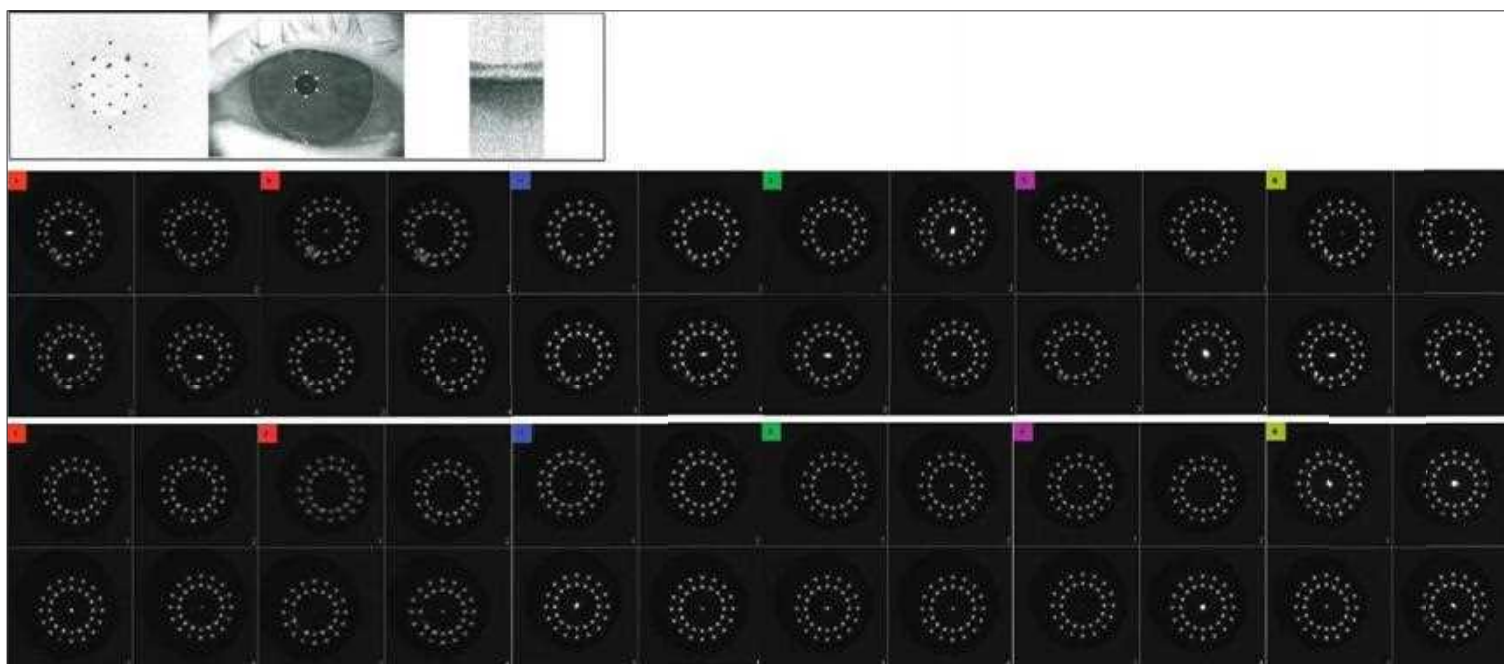

Fig. 5.5.1 Display From the Swept-Source Optical Coherence Tomography Biometer IOLMaster 700.

**Fig. 5.5.2** Poorly reflected LED images from the anterior corneal surface using IOLMaster 700 (top); poorly reflected LED images from the anterior corneal surface using Lenstar with average keratometry and corneal astigmatism of 43.24 D and 2.05 D@174° (middle), and repeated measurements with average keratometry and corneal astigmatism of 44.36 D and 0.25 D@167° (bottom).

Although measurements with optical biometry are mostly operator independent, careful alignment during the scan and inspection of the measurement quality are still necessary for optimal refractive outcomes (Fig. 5.5.2).

The primary limitation of optical biometry is its inability to measure through dense cataracts and other media opacities that obscure the macula. It was reported that with use of an earlier generation of IOLMaster, approximately 10% of eyes could not be accurately measured due to such opacities or fixation difficulties.<sup>6</sup> The IOLMaster 700 showed better penetration in dense posterior subcapsular cataracts, measuring AL successfully in 96% of cases.<sup>5</sup>

## IOL POWER FORMULAS

The first IOL power formula was published by Fyodorov in 1967. Subsequent formulas were developed and traditionally were classified as the second, third, fourth, and newer generations of IOL formulas. Due to the development of more advanced IOL formulas, a new classification based on how they work is more appropriate.

### Vergence Formulas

The majority of IOL formulas are vergence-based formulas. Based on the number of variables they use to calculate ELP, these formulas can be categorized into the following groups:

- **Two-variable formulas:** These include the Holladay 1, Hoffer Q, and SRK/T, and they use AL and keratometry to calculate the distance from the principal plane of the cornea to the thin lens equivalent of the IOL (i.e., ELP). Thus, a short eye or an eye with a flatter cornea will have a shallower anterior chamber. However, Holladay has shown that exceptions to these assumptions exist.<sup>7</sup>
- **Three-variable formula:** The Haigis formula uses AL, keratometry, and ACD.
- **Five-variable formula:** The Barrett Universal II formula uses AL, keratometry, ACD, LT, and WTW.
- **Seven-variable formula:** The Holladay 2 formula uses preoperative refraction, age, AL, keratometry, ACD, LT, and WTW.

### Ray Tracing Formulas

- **PhacoOptics:** With PhacoOptics, IOL power is calculated based on exact ray tracing (Snell's law of refraction). It incorporates the latest generation ACD prediction algorithms based on the complex relationship between the preoperative ocular dimensions (ACD and LT) and the postoperative position of the IOL (postoperative ACD).<sup>8</sup> Measurements

of the anterior and posterior corneal curvatures as along with conic coefficients (Q-values) obtained by modern anterior segment imaging systems can be used directly by the program.

- **Okulix:** Okulix<sup>9</sup> is a program package that calculates single rays using Snell's law. AL can be entered either manually or by a computer link to the measuring device. As an alternative to entering corneal radii by hand, they also can be taken from a two-dimensional corneal topographic map.

## Artificial Intelligence Formulas

- **Radial basis function (RBF):** The Hill-RBF calculator<sup>10</sup> is an advanced, self-validating method for IOL power selection employing pattern recognition and a sophisticated form of data interpolation. Based on artificial intelligence, this methodology is entirely data driven. Pattern recognition for selecting an IOL power is achieved through the process of adaptive learning, the ability to learn tasks based solely on data. Unlike static theoretical formulas, this approach will be an ongoing project and continuously updated as a "big data" exercise. The greater the number of surgical outcomes that are fit to the RBF model, the greater the overall depth of accuracy.
- **Neural network:** Clarke<sup>11</sup> developed a computational method based on neural network in which the software is trained to predict IOL powers using large amount of clinical data from one surgeon with one IOL. Clinical data include preoperative AL, keratometry, ACD, and LT.

## Combination Formulas

- **Super formula:** The Ladas super formula<sup>12</sup> amalgamates outcomes from the above-mentioned two-variable and three-variable vergence formulas and has a small component of artificial intelligence.

All of these formulas have some element of regression, as they include constants that are derived from prior patient outcomes. Note that two critical data points are not measured: posterior corneal curvature (although this is slowly being integrated) and ELP. Better predictive formulas for estimating ELP will likely require more sophisticated measurements, possibly to include lens diameter, lens volume, and certain angle and iris features.

## IOL CALCULATIONS IN SPECIAL EYES

### IOL Power Calculation in Short Eyes

In short eyes, the importance of accurate ELP prediction is magnified due to the high power of the IOL and the relatively short distance from the IOL to the retina. Olsen<sup>13</sup> showed that 0.25 mm error in postoperative ACD

corresponds to a 0.1 diopter (D) error in long eyes with 30 mm AL and a 0.5 D error in short eyes with 20 mm AL.

In IOL calculation formulas that do not use ACD in the ELP calculation, it is assumed that short eyes have a proportionally shallower anterior chamber. However, this assumption breaks down in the many short eyes that in fact have normal anterior chamber anatomy with normal ACD.

Several studies in the literature have compared different IOL power formulas and their accuracy in short eyes. Although it is believed that newer IOL power prediction formulas perform best in short eyes, uncertainty still exists in the literature on whether any of the available formulas perform better than the others.<sup>14–16</sup>

In general, our approach for short eyes is to use the Holladay 1, Holladay 2, Hill-RBF, Olsen, and Barrett, favoring the Olsen when there is disagreement. We also try to operate on the nondominant eye first so that we can use its refractive outcome to adjust the IOL power for the second eye, generally changing the calculated IOL power by one-half of the prediction error in the first eye.

## IOL Power Calculation in Long Eyes

In long eyes, IOL power formulas tend to select IOLs of insufficient power, leaving patients with postoperative hyperopia. Inaccurate measurement of preoperative AL has been reported to be the main reason for postoperative refractive error in axial high myopia.<sup>17</sup> The incidence of posterior staphyloma increases with increasing AL. Ultrasonic biometric methods can produce errors in the presence of a posterior staphyloma by giving falsely long AL.

Theoretically, optical biometry permits more accurate measurements when a posterior staphyloma is present. However, in a study investigating the accuracy of SRK/T formula in eyes with negative or zero-powered IOLs, MacLaren and colleagues<sup>18</sup> reported consistent hyperopic errors across all three methods of biometry (A-scan, B-scan, and optical). This indicates that eliminating or minimizing the adverse impact of posterior staphylomata on IOL calculations does not prevent hyperopic surprises in long eyes.

We proposed a method for optimizing AL in long eyes (Wang–Koch adjustment).<sup>19</sup> Our results showed that this method significantly improved the accuracy of IOL power calculation in eyes with IOL powers  $\leq 5.00$  D and significantly reduced the percentage of eyes that would be left hyperopic. We recommend using the optimized AL in eyes with AL  $> 25.2$  mm. Based on the formula, the optimized AL is calculated from the measured optical or ultrasonic AL using the following equation:

$$\text{Holladay 1 Optimized AL} = 0.8289 \times \text{Measured AL} + 4.2663$$

$$\text{Haigis Optimized AL} = 0.9286 \times \text{Measured AL} + 1.562$$

$$\text{SRK/T Optimized AL} = 0.8544 \times \text{Measured AL} + 3.7222$$

$$\text{Hoffer Q Optimized AL} = 0.853 \times \text{Measured AL} + 3.5794$$

Then the optimized AL is entered into the IOLMaster or Lenstar and the calculation is performed again. We recommend selecting the IOL power that predicts a minus prediction error close to zero ( $-0.1$  to  $-0.2$  D), since slight myopic results may occur with this approach of optimizing AL.

A recent advance has been the development of the Barrett Universal II formula, which has been refined to improve outcomes in long eyes. In a study of eyes with AL  $\geq 26.0$  mm, Abulafia et al.<sup>20</sup> reported that for IOL powers  $< 6.00$  D, best results occurred with the Holladay 1 with Wang–Koch adjustment, Haigis with Wang–Koch adjustment, and Barrett Universal II formulas.

Due to the low IOL powers required in long eyes, accuracy of ELP estimation is not as important as in normal and short eyes. By refining the AL value used in current formulas, excellent outcomes can be anticipated as shown in these studies.<sup>19,20</sup>

## IOL Power Calculation in Eyes With Previous Corneal Refractive Surgery

Cataract surgeons are facing challenges in IOL power calculation in eyes that have undergone excimer laser photorefractive keratectomy (PRK), laser in situ keratomileusis (LASIK), or radial keratotomy (RK).

## Factors Contributing to Challenges in IOL Power Calculation

There are two factors that primarily contribute to challenges in IOL power calculations in eyes with previous LASIK, PRK, or RK: difficulties in obtaining accurate corneal refractive power and problems in ELP prediction. Following LASIK/PRK/RK, the predicted ELP would be misleading if the postoperative corneal power were used in the ELP calculation. To avoid the ELP-related IOL prediction error, Aramberri proposed the double-K method.<sup>21</sup> With the double-K version of the IOL formulas, the prerefractive surgery corneal power is used to estimate the ELP and the postrefractive surgery corneal power is used to calculate the IOL power. This approach had been previously used by Holladay in his Holladay Consultant Program. Several studies have shown that the double-K method improves the accuracy of IOL power calculation after LASIK/PRK.<sup>21–23</sup>

## Methods to Improve the Accuracy of IOL Power Calculations in Postrefractive Eyes

Many approaches have been proposed to improve the accuracy of IOL power calculation in eyes following LASIK/PRK/RK. These can be categorized into three groups depending on the use of historical data acquired before refractive surgery was performed.

### Methods Relying on Prior Clinical Data

Methods in this category use completely historical data. Clinical studies have shown that they are less accurate than the formulas in other categories described in the following sections.<sup>24</sup> The concern with these methods is their sensitivity to errors in the historically obtained data. A 1.00 D error in either the keratometric or refractive values translates to nearly a 1.00 D postoperative refractive error.

### Methods Using a Combination of the Surgically Induced Refractive Change ( $\Delta$ MR) and Current Corneal Power Values

These methods modify either corneal power measurements at the time the patient presents for cataract surgery or calculated IOL power based on  $\Delta$ MR.

These methods multiply  $\Delta$ MR by a fraction of between 0.15 and 0.33, depending on the formula. This translates to an error of 0.15–0.33 D for each 1.00 D of error in  $\Delta$ MR, reducing potential errors caused by having inaccurate historical data. Studies have shown that some of these methods have consistently been among the more accurate approaches.<sup>24</sup>

### Methods Requiring No Historical Data

Several methods requiring no historical data have been proposed. Surgeons use these approaches most often. The formulas fall into two categories:

- Formulas that adjust measured corneal power from the anterior corneal surface based on either regression analysis or assumed posterior corneal power, such as the Wang–Koch–Maloney, Shammas, Haigis-L, Potvin-Hill Pentacam, and Barrett True K No History formulas.
- Formulas based on corneal power measurements from both anterior and posterior corneal surfaces. Using the RTVue (Optovue Inc, Fremont, CA), Tang and colleagues<sup>25</sup> developed an OCT-based IOL calculation formula using the anterior and posterior corneal powers and the central corneal thickness.

Methods requiring no historical data have been shown to perform as well as those using a combination of  $\Delta$ MR and current corneal power values. Promising results for the OCT-based IOL formula and Barrett True K formula have been reported.<sup>26,27</sup> However, the percentage of eyes within 0.5 D of target refraction was under 70% for all formulas, the highest value being 68.3% for the OCT formula. Obviously, more studies are needed to improve the accuracy of corneal power measurements and to develop new IOL power calculation formulas in these eyes.

### Web-Based Post-Refractive IOL Calculator

To simplify the complicated and time-consuming calculations discussed above, we developed a web-based post-refractive IOL power calculator in 2007 (Fig. 5.5.3) (<http://www.ascrs.org/>). This calculator can be used for eyes with previous myopic LASIK/PRK, hyperopic LASIK/PRK, or RK. We have performed major updates to the online calculator in the past and will continue to update it. During the past year, the number of visits to this calculator was over 120,000.

### Radial Keratotomy

IOL power calculation in RK eyes is even more difficult due to the greater irregularity of the anterior corneal curvature and the posterior corneal

curvature changes. Furthermore, it has been reported that 20%–50% of RK eyes have a gradual hyperopic shift. We recommend using topographically derived average corneal power over the central 2–4 mm zone. Compensation for potential error in ELP is still required, with use of double-K version of IOL formulas if the corneal power is used for ELP prediction.

We find relatively lower accuracy in post-RK eyes compared with eyes following LASIK/PRK. In 95 post-RK eyes, we<sup>28</sup> evaluated the accuracy of newer IOL formulas (OCT and Barrett True K), and the percentage of eyes within 0.5 D of target was less than 50% for all formulas. Further

IOL calculations are more difficult in eyes with keratoconus, presumably due to the irregularity of the cornea and the change in ratio of anterior to posterior corneal curvatures. Using the Holladay 1, Barrett, and Olsen

formulas in 21 keratoconic eyes, we found that the mean refractive prediction errors were +1.25 D, +1.15 D, and +1.36 D, respectively, and the magnitude of the hyperopic prediction error with Holladay 1 formula increased with increasing corneal power. Improved corneal imaging technology for accurate anterior and posterior corneal power measurements is needed.

## IOL Power Calculation in Eyes Following Keratoplasty

Eyes following penetrating keratoplasty may have high amounts of irregular anterior corneal astigmatism and uncertain posterior corneal values. With Descemet's stripping automated endothelial keratoplasty, corneal power changes are less pronounced with minimal astigmatic change but with a hyperopic shift of around 0.70–1.5 D. Descemet membrane endothelial keratoplasty induces even more modest refractive changes, with a reported hyperopic refractive shift of 0.24–0.50 D and minimal change in refractive astigmatism. Although the complexity of IOL calculation has diminished as procedures have advanced, it remains challenging to perform IOL power calculation in these eyes.

## TORIC IOL CALCULATION

It has been estimated that 30% of cataract patients have more than 0.75 D of corneal astigmatism. Toric IOLs provide consistent and stable correction of astigmatism. Accurate measurement of total corneal astigmatism is a critical element in correcting astigmatism during cataract surgery.

## Impact of Posterior Corneal Astigmatism

Newer technologies, such as Scheimpflug devices and OCT systems, are now used in the clinical setting for measuring the posterior corneal surface. Several studies using different methodologies reported that the posterior cornea has astigmatism that ranges from 0.26 to 0.78 D.<sup>29,30</sup> There were three new findings in our study<sup>30</sup>: (1) in corneas with anterior corneal with-the-rule (WTR) astigmatism, as astigmatism increases, the posterior cornea is increasingly steep vertically; (2) posterior corneal astigmatism is relatively constant in corneas with anterior against-the-rule (ATR) astigmatism; and (3) much individual variability occurs in posterior corneal astigmatism, exceeding at extremes over 0.5 D.

## Selection of Toric IOL Toricity

Several approaches are available to guide the selection of IOL toricity:

- **Baylor Toric IOL Nomogram:** Using regression analysis,<sup>31</sup> we developed the Baylor Nomogram (Table 5.5.1). It provides a clinical method to compensate for posterior corneal astigmatism as a function of the meridian and magnitude of anterior corneal astigmatism.
- **Abulafia–Koch Formula:** Based on outcomes of patients implanted with toric IOLs, Abulafia–Koch<sup>32</sup> proposed an improved regression formula to refine the precision of incorporating the posterior corneal astigmatism into toric IOL planning. This has been incorporated in the new Hill-RBF calculator that is available on the Lenstar.

**TABLE 5.5.1 Baylor Toric IOL Nomogram<sup>a</sup> (Postoperative Target: Up to 0.40 D With-the-Rule Astigmatism)**

Effective IOL Cylinder Power at Corneal Plane (D)	WTR (D)	ATR (D)
0 <sup>b</sup>	≤1.69 (PCRI)	<0.39
1.00	1.70–2.19	0.40 <sup>a</sup> –0.79
1.50	2.20–2.69	0.80–1.29
2.00	2.70–3.19	1.30–1.79
2.50	3.20–3.69	1.80–2.29
3.00	3.70–4.19	2.30–2.79
3.50	4.20–4.69	2.80–3.29
4.00	4.70–5.19	3.30–3.79

ATR, Against-the-rule astigmatism; D, diopter; PCRI, peripheral corneal relaxing incision; WTR, with-the-rule astigmatism.

<sup>a</sup>Values in the table are the vector sum of the anterior corneal and surgically induced astigmatism.

<sup>b</sup>If an SN6AT2 is available, consider implanting it in WTR astigmatism of 1.40–1.69 D, and in ATR of 0.30–0.49 D (in this latter case, T3 would be implanted in astigmatism ranging from 0.50–0.79 D).

- **Barrett Toric Calculator:** This calculator predicts posterior corneal astigmatism based on regression analysis in patients implanted with toric IOLs.
- **Holladay Toric Calculator:** With this calculator, IOL spherical power and the predicted ELP in each eye are used to estimate the effective IOL cylinder power at the corneal plane. It has the option to use the Baylor nomogram to take into account posterior corneal astigmatism.
- **Toric calculators provided by manufacturers:** The Alcon toric calculator uses the Barrett toric calculator. The Johnson & Johnson toric calculator is based on outcomes of their clinical studies combined with the Baylor nomogram. The PhysIOL toric calculator integrates the Abulafia–Koch formula to account for posterior corneal astigmatism when standard keratometry are used.

When selecting the IOL toricity, several factors must be taken into account:

- The cylindrical power of the toric IOL should be chosen based on the total corneal astigmatism, taking into consideration anterior and posterior corneal astigmatism and surgically induced astigmatism.
- The impact of ELP and IOL power on the effective cylinder power of the IOL at the corneal plane should be considered. Effective toricity of the IOL diminishes with increasing ACD and lower IOL spherical power.
- It is desirable to leave patients with a slight WTR astigmatism due to the normal tendency for corneal astigmatism to drift ATR with advancing age.<sup>33</sup>

Abulafia et al.<sup>34</sup> reported that with the Barrett toric calculator, 75% and 100% of eyes were within  $\pm 0.50$  D and  $\pm 1.00$  D of the predicted residual astigmatism, respectively. In another study, Abulafia et al.<sup>32</sup> evaluated and compared the accuracy of two toric IOL calculators (the original Alcon toric calculator and the Holladay toric calculator) with or without the Abulafia–Koch formula. Results showed that adjustment of these commercial toric IOL calculators by the Abulafia–Koch formula significantly improved the prediction of postoperative astigmatic outcome with 76.9%–78.2% of eyes within  $\pm 0.5$  D and 97.4%–98.7% within  $\pm 1.00$  D.

## Imaging and Guidance Systems for Toric IOL Alignment

Accurate toric lens alignment at the desired meridian is crucial to achieve effective astigmatism correction. When a toric IOL is misaligned, a reduction occurs in the cylinder correction along the desired meridian and induction of cylinder at a new meridian.

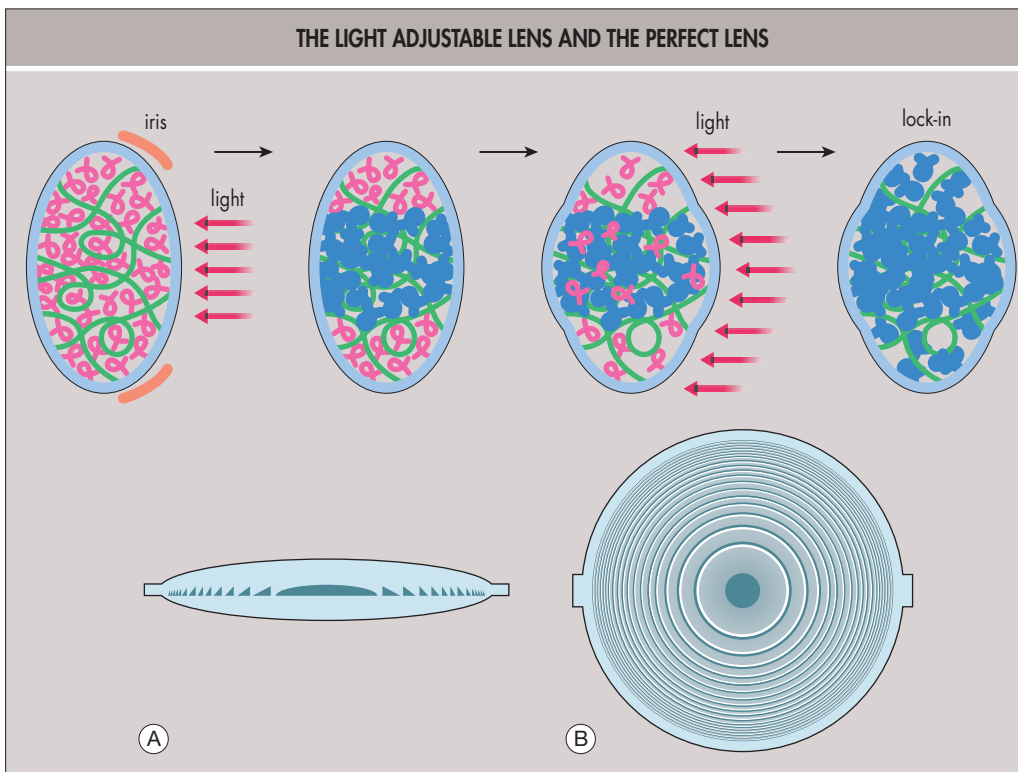

Traditionally, the eye is manually marked preoperatively. With advances in technology, several imaging and guidance systems for toric IOL alignment have been developed:

- **TrueVision 3D visualization and guidance system (TrueVision 3D Surgical, Santa Barbara, CA):** The Cassini topographer (i-Optics, The Hague, Netherlands) is used to obtain an image of the patient's eye preoperatively. This source image is then uploaded to the TrueVision system in the operating room for intraoperative registration.

In a recent study, we evaluated the accuracy of toric IOL alignment in femtosecond laser-assisted cataract surgery using the TrueVision system compared with manual marking combined with femtosecond laser marks.<sup>35</sup> No significant difference existed between these two methods.

- **Callisto eye system (Carl Zeiss Meditec, Jena, Germany):** Preoperatively, an image of the eye is taken along with keratometry measurements using the IOLMaster. Both the reference images and keratometry data are transferred to the Callisto eye computer-assisted surgery system. The toric assistant feature, Z ALIGN, uses the reference axis from the IOLMaster and the projected target axis in the microscope eyepiece to ensure toric IOL alignment.
- **VERION image guided system (Alcon Laboratories, Ft. Worth, TX):** This system is composed of the Reference Unit and the Digital Marker. The Reference Unit measures both keratometry and pupil size and captures a high-resolution reference image of the eye that is used for intraoperative tracking and registration. The Digital Marker uses the preoperative image and intraoperative registration to guide toric IOL alignment.

Elhofi and Helaly<sup>36</sup> compared clinical outcomes following toric IOL alignment with digital image guidance using the VERION and manual slit-lamp-assisted preoperative marking. The use of the VERION system resulted in less postoperative deviation from the targeted astigmatic axis.

**Fig. 5.5.4 The Light Adjustable Lens and the Perfect Lens.** **Top:** Exposure to targeted ultraviolet light in the Light Adjustable Lens resulting in a predictable shape change and subsequent locking of the treatment. **Bottom:** (A) Side view of the Perfect Lens and (B) top view of the Perfect Lens. The concentric diffractive zones are visible.

All of these automated systems using anatomic or topographic landmarks to guide toric IOL alignment seek to decrease the inherent error associated with preoperative manual marking alone. As our study showed, manual marking can achieve accuracy that matches the automated systems, but the latter clearly have the advantage of greater convenience. However, there is still a need for clinical studies assessing the efficacy of each of these systems.

## INTRAOPERATIVE WAVEFRONT ABERROMETRY

Intraoperative wavefront aberrometry is a tool designed to fine-tune cataract surgery results through aphakic refraction. It allows the surgeon to confirm or revise the IOL power, confirm or rotate the toric IOL meridian, titrate limbal relaxing incisions, and open penetrating relaxing incisions. Currently, there is only one commercially available device:

- **Optiwave Refractive Analysis (ORA) system (WaveTec Vision Systems Inc, Aliso Viejo, CA):** Using infrared light and Talbot-Moiré interferometry, the ORA system measures the aphakic refraction intraoperatively after cataract extraction. The system calculates the optimal IOL power based on the aphakic spherical equivalent, the patient's preoperatively measured AL and keratometry, and the estimated ELP using a proprietary algorithm.

In 246 myopic LASIK/PRK eyes, Ianchulev and colleagues<sup>37</sup> reported that ORA achieved the greatest predictive accuracy compared to Haigis-L and Shammas method, with 67% of eyes within 0.5 D and 94% within 1.00 D of the predicted outcome. Fram et al.<sup>38</sup> compared the accuracy of ORA, OCT-based formula, Haigis-L, and Masket formula in LASIK/PRK eyes. There was no significant difference among the methods.

The aphakic refractive data obtained with intraoperative aberrometry devices take into account a variety of factors, such as the posterior corneal astigmatism. However, these measurements have two limitations: (1) ELP cannot be measured with these devices and has to be estimated, and (2) the cornea and perhaps other factors have been modified by the drops and surgical trauma. Further studies are desirable to evaluate the performance of intraoperative wavefront aberrometry in patients undergoing cataract surgery.

## POSTOPERATIVE IOL ADJUSTMENT

The "holy grail" in this field may be an adjustable IOL. Once the postoperative refraction has stabilized, the IOL could be modified to eliminate the residual spherical and astigmatic refractive errors and residual

higher-order aberrations. Ideally, such an IOL could be modified multiple times to adapt to patient's changing visual needs and to compensate for aging changes of the cornea.

The Light Adjustable Lens (LAL; Calhoun Vision, Pasadena, CA) (Fig. 5.5.4) enables residual spherical and cylindrical errors to be corrected or adjusted after the postoperative refraction has stabilized.<sup>39–41</sup> In 34 myopic LASIK/PRK eyes, Brierley<sup>39</sup> reported that LAL produced refractive prediction errors within 0.25 D in 74% of eyes, 0.50 D in 97% of eyes, and 1.00 D in 100% of eyes. Villegas and colleagues<sup>40</sup> found that the combination of two light adjustments induced a maximum change in spherical power of the LAL of between  $-1.98$  D and  $+2.30$  D and in astigmatism of up to  $-2.68$  D with axis errors below  $9^\circ$ .

Another adjustable IOL under development is the Perfect Lens (Perfect Lens, LLC, Irvine, CA) (see Fig. 5.5.4). This technology involves using a femtosecond laser to modify the hydrophilicity and thus the refractive index and refractive characteristics of defined zones within a standard IOL. Changing the relative heights and profiles of the concentric refractive zones with the femtosecond laser enables modification of IOL spherical aberration, asphericity, toricity, and multi-focality with a repeatable, in-office procedure. In a study by Sahler et al., Perfect Lens technology altered the power of the IOL to within 0.1 D of the targeted change without decreasing the optical quality of the lens.<sup>42</sup>

## CONCLUSION

Optical biometry is the clinical standard for ocular biometry. With advanced IOL power calculation formulas, the accuracy of IOL power prediction has improved dramatically in recent years. However, refractive surprises still occur, especially in eyes with previous corneal refractive or endothelial replacement surgery.

In these challenging cases, we warn patients of IOL power calculation inaccuracy and the possible need for additional surgery, with its associated cost. The most prudent strategy for the surgeon may be to obtain IOL calculations using several different methods and select the IOL power based on the consensus of multiple methods. Future advances are needed in all areas, including methods of measuring corneal power, predicting effective lens position, and calculating the lens power.

# Indications for Lens Surgery/Indications for Application of Different Lens Surgery Techniques

Frank W. Howes

## 5.6

**Definition:** Surgery to the crystalline lens of the eye.

### Key Features

- Lens surgery is the most common eye operation.
- Technical indications for lens surgery are divided into two main categories: medical and optical.
- All lens surgery for whatever indication should be considered refractive surgery.

## INTRODUCTION

The indications for lens surgery today may be classified into two main categories:

- Medical – surgical or pathological indication, and
- Optical – or refractive lens exchange.

Medical indications arise from pathological states of the lens of varying causes, usually related to lens clarity, lens position, or other lens-related conditions, such as inflammation, glaucoma, or the threat of glaucoma. Surgical or pathological indications have existed for centuries, if not millennia, and are generally indisputable. Refractive indications for lens surgery, in contrast, include clear lens ametropic refractive states. The current high standards of lens surgery in terms of safety, accuracy, and customization have opened a new world of refractive correction for many patients who were previously considered untreatable. Lens surgery has found an indisputable position in refractive surgery among the various competitors of laser surgery, phakic IOL (intraocular lens) surgery, and incisional corneal surgery. As customization has improved for each age group and each refractive error group, so have the various treatment modalities expanded or contracted with respect to patient safety and accuracy of outcome.

## MEDICAL INDICATIONS FOR LENS SURGERY

### Lenticular Opacification (Cataract)

The medical indications for lens surgery (Box 5.6.1) are true pathological states, some of which may threaten the integrity of the whole organ (the eye). They also interfere with a major ocular function: focused vision. Lenticular malformation and opacification obstruct the pathway of light; reduce the available quantity of light; scatter light off axis; reduce contrast sensitivity; diminish color intensity; reduce resolution acuity; may alter lens texture in such a way as to contribute to a decrease in accommodation amplitude, particularly in the case of presenile nuclear sclerosis; and, in the case of progressive nuclear sclerosis, often result in a myopic alteration of a previously stable lifelong refractive state.

It is generally agreed that surgical intervention is indicated when there is “functional” visual impairment.

The boundary between refractive surgery and cataract surgery remains somewhat blurred, especially in view of the variable nature of what patients deem loss of “functional” vision. A boundary, however, is necessary for the

### BOX 5.6.1 Medical Indications for Lens Surgery

- I. Lenticular opacification (cataract)
- II. Lenticular malposition
  - A. Subluxation
  - B. Dislocation
- III. Lenticular malformation
  - A. Coloboma
  - B. Lenticonus
  - C. Lentiglobus
  - D. Spherophakia
- IV. Lens-induced inflammation
  - A. Phacotoxic uveitis (phacoanaphylaxis)
  - B. Phacolytic glaucoma
  - C. Phacomorphic glaucoma
- V. Lenticular tumor
  - A. Epithelioma
  - B. Epitheliocarcinoma
- VI. Facilitatory (surgical access)
  - A. Vitreous base
  - B. Ciliary body
  - C. Ora serrata

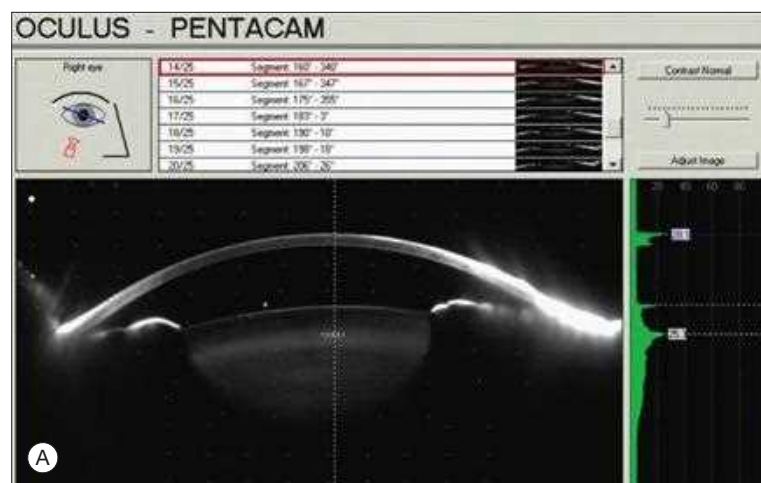

separation in terms of insured payments. The degree to which the opacification obstructs light can, additionally, be measured by laser interferometry.<sup>1</sup> Progressive changes in cataract density over time can be documented by slit-lamp estimation using the Lens Opacification Classification System (LOCS-III) devised by Chylack and coworkers,<sup>2</sup> by Scheimpflug photography of nuclear cataracts<sup>3</sup> and by Neitz-Kawara retroillumination photography of posterior sub-capsular cataracts.<sup>4</sup> A useful figure to use for cataract/noncataract separation is approximately 20% opacification on Pentacam Scheimpflug densitometry (Fig. 5.6.1).<sup>5</sup>

### Cataract in the Presence of Other Ocular Disorders

The decision regarding whether and when to remove a cataract in an otherwise healthy eye usually depends on the impact of the cataract on the visual function of the eye and the impact of that level of visual impairment on the person's life. The status of the other eye also is important. In healthy eyes whose only disorder is cataract, the presumed outcome after uncomplicated surgery is better vision than before surgery. Indeed, in high-volume cataract units, a success rate of 98% can be expected. Thus when one applies a risk-benefit ratio with such a high degree of success, surgery is usually the mutually agreed upon course.

However, such may not be the case when the cataract is associated with other disorders, especially if they are contributing factors to the loss of vision of an eye. Therefore, such conditions as amblyopia, corneal opacification, vitreous opacification, maculopathy, retinopathy, glaucoma, and optic neuropathy may alter or delay the decision to operate, based not so much on the expected risks but rather on the limited benefits. In some cases, lens surgery is indicated to preserve peripheral vision only for functional ambulation. In other cases, maintenance of a posterior segment view for treatment purposes in progressive posterior segment conditions is an indication for lens surgery, even when the expectation for visual

**Fig. 5.6.1** Pentacam Scheimpflug densitometry (A) and slit-lamp imagery of Lens Opacification Classification System III NO3 cataract (B). (Courtesy Dr Lee Lenton, Vision Eye Institute Australia.)

improvement may be minimal.<sup>11</sup> Also, if the other eye is blind, the surgery may be delayed.

Systemic conditions may play a role in deciding whether and when to remove a cataract. Is the patient's diabetes under control? Has there been a stroke with hemianopia? Is the patient on systemic anticoagulants? Is the patient terminally ill or immunologically suppressed? Does the patient have Alzheimer's disease or severe co-operation difficulty?

Thus, the decision to remove a cataract may become a collaborative endeavor, with participation by the patient, the patient's family, the patient's primary physician, the surgeon, a governmental agency, and a third-party payer. The decision, therefore, is determined not only by technological findings and expectations, but also by a "holistic" evaluation of the impact of such a decision on that person's life, as defined by that society. Various tests are available to assess degrees of disability, such as the Visual Function Index (VF-14)<sup>6-9</sup> or the Activities of Daily Vision Scale (ADVS).<sup>10,11</sup>

## Lenticular Malposition

Subluxation (the displacement of the lens within the posterior chamber) and dislocation (displacement of the lens out of the posterior chamber into the anterior chamber or vitreous) of the lens are different degrees of the same phenomenon and result from dysfunction of the zonules. The zonules may be defective as a result of congenital malformation, total or partial agenesis, or a hereditary metabolic disorder, such as Marfan's syndrome. Chronic inflammation and pseudoexfoliation have been shown to be associated with a weakness in the zonular fibers or their attachments. Ocular trauma is an obvious cause. Subluxation, in the absence of associated sequelae, may not be visually significant and may not be an indication for lensectomy. Similarly, complete dislocation of an intact lens into the inferior vitreous may be a quiescent event in the absence of inflammation and may simply produce a state of refractive aphakia, correctable nonsurgically with a spectacle or contact lens or surgically with IOL implantation. Subluxation to the extent that the equator of the lens is visible in the mid-sized pupil is usually visually significant, causing glare, fluctuating vision, and monocular diplopia. This symptom complex would qualify for lens surgery.

## Lenticular Malformation

These conditions of abnormal lens development are congenital. They may be genetic, hereditary, or the result of intrauterine infection or trauma. These conditions include lens coloboma, lenticonus, lentiglobus, and spherophakia, as well as varieties of congenital cataract, such as rubella and Lowe's syndrome. Partial iris coloboma or total aniridia, whether congenital, traumatic, or surgical, may be an indication for lens surgery to improve visual function or for cosmesis. The availability of aniridia IOLs (Fig. 5.6.2A) and opaque endocapsular rings (see Fig. 5.6.2B,C) offers great improvements for such patients.

The indications for surgery depend on the degree to which the specific malformation interferes with vision or the integrity of the involved eye. Such abnormalities may be associated with amblyopia. Early detection and surgical intervention should be incorporated with a plan for amblyopia therapy.

## Lens-Induced Ocular Inflammation

Phacoanaphylactic endophthalmitis (phacotoxic uveitis) occurs in an immunologically mature and competent host and is related to physical or chemical disruption of the lens capsule. Surgery may be the appropriate treatment for this form of ocular inflammation.

## Lens-Induced Glaucoma

### Inflammatory Glaucoma (Phacolytic Glaucoma)

Phacolytic glaucoma occurs in an eye with a mature lens in which the lens capsule is intact. Denatured, nonantigenic liquefied lens material leaks out through the intact lens capsule and elicits a macrophagic, inflammatory reaction. The macrophages, engorged with lens material, clog the open angle, leading to a secondary open-angle glaucoma. Removal of the lens and intraocular lens placement is usually curative, obviating the need for other forms of medical or surgical pressure management.

### Pupil Block and Angle Closure (Phacomorphic Glaucoma)

Similarly, removal of the lens in this instance is also curative. The growth of the lens with age progressively engulfs anterior segment space and may ultimately lead to acute angle-closure glaucoma through the mechanism of pupillary block. This is more likely in hyperopic eyes due to the short axial length and already crowded anterior segments. Lens removal and replacement with an intraocular lens greatly increases anterior segment space and in most instances resolves the glaucoma.

## REFRACTIVE INDICATIONS FOR LENS SURGERY

Refinements in measurement technology, ocular anesthesia, incision technology, lensectomy techniques, ophthalmic viscosurgical devices (OVD) tissue protection, and IOL technology has allowed the accurate and successful correction of refractive errors.

Almost all the operable tissues and spaces of the eye have, over decades, come under investigation as locations for refractive surgical modulation: corneal epithelial surface, corneal stroma, corneal endothelial surface, anterior chamber, iris, pupil, posterior chamber, lens, and sclera. The lens, therefore, assumes its role among the others as a popular location for surgical refractive modulation, sparing the other tissues where appropriate or necessary.

Clear lens replacement stands as a viable procedure today for both myopia and hyperopia, with the abilities now to control astigmatism (Fig. 5.6.3A),

**Fig. 5.6.2 Iris Defect Prostheses.** (A) Aniridia intraocular lens with opaque peripheral "pseudiris." (B) Aniridia endocapsular ring. (C) Iris coloboma endocapsular ring (diaphragm type 96G). (Courtesy Morcher, GmbH, Germany.)

(Courtesy C&C Inc.)

modulate higher-order aberration (see Fig. 5.6.3C), and reduce presbyopic symptoms (see Fig. 5.6.3B,E). Patient demand for these services has increased dramatically in recent times.

Multifocal IOLs (see Fig. 5.6.3B) represent some of the first attempts at the intraocular correction of presbyopia. Other attempts at the development of a truly accommodative pseudophakos have included the intracapsular injection of liquid silicone<sup>12-14</sup> and the intracapsular placement of high-water-content poly-HEMA lenses,<sup>15</sup> a liquid silicone-filled intracapsular balloon,<sup>16,17</sup> multiple IOLs (polypseudophakia)<sup>18,19</sup> (see Fig. 5.6.3D), and the flexing haptic accommodative IOLs (see Fig. 5.6.3E).

## INDICATIONS FOR DIFFERENT LENS SURGERY TECHNIQUES

Surgery affecting the human lens can be organized historically by its chronology of development (Table 5.6.1) or divided into four major categories by technique (Box 5.6.2). The indications for a particular lens surgery technique may be determined by several factors (Box 5.6.3). Different medical conditions or pathological states of the eye and the lens may favor one technique over another. In some countries, the availability of equipment and the level of training of the surgeon may be factors that dictate technique. Certain countries have governmental agencies, professional organizations, academic institutions, insurance payers, or surgical facilities that regulate and control the types of surgical techniques surgeons may perform. For the purpose of this text, however, only specific medical or pathological conditions of the eye are discussed as factors determining the choice of surgical technique.

### Intracapsular Cataract Extraction

The intracapsular cataract extraction (ICCE) method of lens removal has not been the procedure of choice in industrialized nations since the

**TABLE 5.6.1 History of Cataract Surgery Techniques**

Year	Technique	Place	Surgeon
800	Couching	India	Unknown
1015	Needle aspiration	Iraq	Unknown
1100	Needle aspiration	Syria	Unknown
1500	Couching	Europe	Unknown
1745	ECCE inferior incision	France	Daviel
1753	ICCE by thumb expression	England	Sharp
1860	ECCE superior incision	Germany	von Graefe
1880	ICCE by muscle-hook zonulysis and lens tumble	India	Smith
1900	ICCE by capsule forceps	Germany	Verhoeff Kalt
1940	ICCE capsule suction erysiphake	Europe	Stoewer I. Barraquer

ECCE, Extracapsular cataract extraction; ICCE, intracapsular cataract extraction; IOL, intraocular lens.

### BOX 5.6.2 Lens Surgery Techniques

- I. Lens repositioning (“couching”)
  - A. Extracapsular
  - B. Intracapsular
    1. Physical (instrumental) zonulysis
    2. Pharmacological (enzymatic) zonulysis
- II. Lens removal
  - A. Total (intracapsular)
    1. Capsule forceps
    2. Suction erysiphake
    3. Cryoextraction
  - B. Partial (extracapsular)
    1. Anterior capsulotomy/capsulectomy
      - a. Discontinuous
      - b. Continuous (capsulorrhexis)
      - c. Linear
    2. Nucleus removal
      - a. Assembled delivery (large incision)
        - (1) Expression (“push”)
        - (2) Extraction (“pull”)
      - b. Disassembled extraction
        - (1) Phacosection
        - (2) Phacoemulsification-aspiration
          - (a) Ultrasound
            - (i) linear
            - (ii) torsional
          - (b) Laser
          - (c) Water jet
          - (d) Impeller
      3. Cortex removal
        - a. Irrigation
        - b. Aspiration
  - III. Lens replacement (intraocular lens implantation)
    - A. Locations
      1. Anterior chamber
        - a. Angle fixation
        - b. Iris fixation
      2. Pupil
      3. Posterior chamber
        - a. Iris fixation (sutured or enclavated)
        - b. Ciliary sulcus (sutured or unsutured)
    4. Lens capsule
      - a. Anterior capsule
        - (1) Haptic sulcus/optic bag
        - (2) Optic posterior chamber/haptic bag
      - b. Intracapsular (“in the bag placement”)
      - c. Posterior capsule (haptic bag/optic Berger’s space)
    5. Pars plana (sutured)
  - B. Optic materials
    1. Hydrophobic
      - a. Polymethyl methacrylate (PMMA)
      - b. Silicone
      - c. Acrylic
    2. Hydrophilic
      - a. Poly hydroxyethyl methacrylate (poly-HEMA)
      - b. Acrylic
      - c. Collagen-copolymer
  - C. Optic types
    1. Monofocal
      - a. Spherical
        - (1) Plus
        - (2) Minus
      - b. Toric
      - c. Telescopic
      - d. Prismatic
    2. Multifocal
    3. Accommodative
- IV. Lens enhancement: reversal of presbyopia by scleral expansion
  - A. Ciliary cerclage
  - B. Radial anterior ciliary sclerotomy

development of modern extracapsular techniques in the late 1970s, primarily because of lower rates of postoperative posterior segment complications such as hemorrhage, vitreous loss, retinal detachment, and cystoid macular edema. Current indications for planned intracapsular cataract surgery are therefore related only to situations where zonular laxity or deficiency exists and where capsular bag instability is predicted. Under these circumstances, safe and successful extracapsular surgery with intra-ocular lens implant, is often unlikely. Conditions likely to be associated with these conditions are physical trauma to the eye, diseases processes such as Marfans Syndrome and psuedoexfoliation, and isolated congenital anomalies. Significant subluxation or dislocation of the crystalline lens necessitates removal of the entire organ, done either by intracapsular cataract surgery or by pars plana fragmentation and aspiration.

Traditionally, ICCE involved removal of the complete intact lens through a large incision measuring 12–14 mm. In earlier years these eyes were left aphakic, with aphakic spectacle correction offered where available. Bilateral surgery was invariably necessary to minimize aniseikonic problems, although contact lens correction was satisfactory. Many of these eyes have subsequently had secondary IOLs implanted, with the choice of IOL being angle based, iris fixed (anterior or posterior) (see Fig. 5.6.4A), or sutured to the ciliary sulcus.

Modern sulcus fixation IOLs now have design features that enable them to fibrose into the ciliary processes and sulcus (Fig. 5.6.4B), minimizing the chances of posterior dislocation common in previous sulcus fixation IOLs. In addition, these lenses are foldable, allowing small-incision

surgery and adherence to the principles of astigmatism avoidance and correction. In the majority of primary situations for ICCE, the wound needs to be large and hence constructed appropriately for minimization of astigmatism induction.

## Extracapsular Extraction (Large-Incision Nuclear Expression Cataract Surgery)

This technique became popular in the 1980s, as surgeons who had been performing large-incision ICCE and anterior chamber implantation desired the benefits derived from an intact posterior capsule and posterior chamber implantation. The technique persists today and is performed in large numbers, particularly in developing countries, where the more advanced small-incision techniques of phacoemulsification (phaco) and foldable lens implantation are not yet available for the masses.

The only indications for nuclear delivery now relate to (1) hard nuclei that cannot be safely emulsified by phaco and (2) capsule rupture with vitreous presentation mid procedure. Cataracts with high-risk corneas (e.g., Fuchs' endothelial dystrophy, corneal graft) were previously considered to be best dealt with by nuclear expression via continuous linear capsulotomy and intercapsular techniques.<sup>20,21</sup> With optimal use of OVDs ("soft shell")<sup>22</sup> and good technique,<sup>23</sup> however, small-incision procedures are now the procedure of choice.

## Small-Incision Nuclear Expression Cataract Surgery ("Mini-nuc" and Other Techniques)

The indications for these techniques<sup>24,25</sup> relate in the majority to the benefits of smaller incision surgery. Socioeconomic factors and instrumentation availability together with surgeon experience also play a significant part in the choice of this type of surgery.

## Phacoemulsification

This technique of nucleus removal has been performed through incisions ranging from 3.2 mm down to less than 1.0 mm. Combined with foldable lens implantation, the major advantage of phaco is the small incision. Many phaco techniques have been described (Box 5.6.4), as have some nonultrasound techniques<sup>26,27</sup> (of which very few can compete with ultrasound). Current techniques use phaco through self-sealing, sutureless scleral and clear corneal incisions measuring 1.9–3.2 mm. The smaller incisions are astigmatically neutral. These corneal incisions, if made on the steep axis of astigmatism and made wider or moved centrally from the limbus, can be used to titrate the amount of astigmatic correction. These effects can be doubled by making similar incisions on the opposite side of the steep axis on the cornea as well (see Table 5.6.2). The presence therefore of corneal cylinder is an indication for phaco and foldable lens implantation just as is the absence of corneal cylinder. The newest of the cataract surgery techniques involves a combination of techniques, using femtosecond laser-assisted phaco, where the femtosecond laser can cut precise corneal incisions, an accurately sized and truly circular capsulorrhexis and partial fragmentation of the lens nucleus, permitting less

### BOX 5.6.3 Lens Removal Techniques: Ocular Indications

- I. Intracapsular extraction
  - A. Zonular absence/dialysis
  - B. Lens subluxation
  - C. Lens dislocation

ultrasonic energy release.<sup>28,29</sup> Where necessary, this technique can be combined with posterior vitrectomy in a safe manner.<sup>30</sup>

### Surgery of the Lens Capsule

The femtosecond laser currently provides the state of the art for capsulectomy. This capsular opening is software guided, so it is perfectly circular and set to a diameter and position of choice (Fig. 5.6.5). The continuous curvilinear capsulorrhexis or CCC<sup>31</sup> remains the capsulectomy of choice when a femtosecond laser is not available. The size of the capsulectomy is usually approximately 4.5–5.5 mm, sufficient to cover the IOL optic edge for “in the bag” placement of an IOL. The continuous margin of the rhexis provides strength for manipulation during surgery, keeps the IOL in the bag away from the iris pigment, and holds the IOL optic and haptic in position for refractive stability and posterior capsular clarity. Where nucleus expression is required (unusual) and the opening is too small for passage of the nucleus,<sup>34</sup> slits in the rhexis margin may be necessary.

Good view with optimal red reflex is necessary to execute a CCC. When lens maturity is such that no or poor red reflex is present, capsular staining with trypan blue or indocyanine green is most helpful for visualization. Discontinuous capsulorrhexis and inadvertent anterior radial tears or posterior capsular tears can cause vitreous presentation and unwanted IOL complications.<sup>32–34</sup> Care is required where the zonule is weak. Capsulophimosis can occasionally be seen where the zonule is weak or damaged with significant CCC contracture (Fig. 5.6.6A and B). Nd:YAG laser anterior capsular widening may be necessary under these circumstances. Capsular contracture can be vigorous and cause the cessation of accommodative effect in most of the accommodating IOLs currently available. The

**Fig. 5.6.6 Anterior Capsular Fibrosis.** (A) Asymmetric and (B) symmetric anterior capsule fibrosis leading to varying degrees of capsular phimosis. (Courtesy John Shephard, MD, Las Vegas, NV.)

contracture occasionally can be asymmetrical and cause refractive shift (the Calhoun light adjustable IOL<sup>35</sup> can combat these shifts). Usually, however, the contracture onto the new-generation square-edged IOLs designed for the capsular bag maintains posterior capsular clarity.<sup>33</sup> Occasionally the lens epithelial cells (LECs) that induce these changes also migrate behind the IOL, causing posterior capsular pearls and opacity and necessitating Nd:YAG posterior capsulectomy (Fig. 5.6.7). Attempts have been made to destroy remaining LECs with various instruments and chemicals<sup>36–41</sup> but without great success in vivo up to now (Box 5.6.5). Where an IOL requires sulcus fixation in proximity to the posterior iris and pigment, a round anterior edge is necessary to prevent iris chafe, pigment dispersion, and secondary inflammation and glaucoma (Fig. 5.6.8).

### Zonular Surgery

Maintaining adequate zonular strength as well as capsular bag integrity, as discussed earlier, is vital to the long-term stability of an intraocular lens. Occasionally the zonule is segmentally damaged, causing segmental capsular bag laxity and potential surgical difficulty and IOL decentration. A number of surgeons have devised similar devices to stabilise segmental laxity of the capsular bag. These devices called capsular tension rings are inserted into the the fornix of the capsular bag to provide sufficient tension for intra-ocular lens stability and centration. Cionni (Cincinnati, OH) designed modifications to the polymethylmethacrylate capsule tension rings (CTRs) to allow them to be sutured to the eye wall,<sup>42</sup> thus creating a synthetic “pseudozonule” attached to an intracapsular skeletal-supporting apparatus (Fig. 5.6.9A,B,C).

### Surgery for Presbyopia

Many attempts have been made at surgical restoration of accommodation. Many have failed or have had poor outcomes. These range from scleral implants to expand the anterior peripheral sclera in attempts to allow

further space for ciliary action, to accommodative IOL designs placed in the capsular bag. These spectacularly well-engineered devices have regrettably performed poorly in the majority. Substances injected into the capsular bag<sup>38</sup> to restore youthful accommodation have yet to reach the commercial market. Monovision and multifocality remain the mainstay of the surgery for presbyopia. These techniques continue to provide the most satisfactory results with appropriate patient selection. Attempts have been made to use pinhole technology to provide a depth of field where neither

near nor distance acuity is compromised (as incorporated into both corneal inlay and intraocular lens by Acufocus) for those who have difficulty with the compromises of multifocality or those who have difficulty with the anisometropia of monovision. These technologies have been slow to gain momentum as the multifocal technology has shown significant improvement in recent times. Some of the surgical IOL companies have modified their multifocal technologies to soften the distance optical aberrations inherent in this technology at the small expense of a near point pushed slightly further out. Because of significant improvement in the optics of these lenses, companies are using new terms for the extended depth of focus these lenses have instead of the term multifocal. Research continues in this field to maintain an extended depth of focus without penalty of aberration.

### Monovision

Monovision is the state of anisometropia geared toward emmetropia in one eye (usually the dominant eye) and near-weighted ametropia (myopia) usually in the nondominant eye. Strictly optically speaking, a myopic outcome of  $-3.00$  diopters (D) would provide a near focal point at 33 cm. This amount of anisometropia would in many instances produce asthenopic symptoms. In practice, patients need only small amounts of residual myopia to be able to read and perform near visual tasks.

The target refraction, which in the nondominant monovision reading eye provides the best reading acuity with the least distance acuity loss and with least anisometropic asthenopia, is between  $-0.75$  D and  $-1.50$  D. This amount of ametropia, particularly when blended with a small amount of aspherical defocus<sup>43</sup> provides the easiest rehabilitation for the monovision patient while maintaining a reasonable amount of near and intermediate visual acuity. In spite of these guidelines, patients should still undergo, at the very least, a loose lens (trial frame) demonstration of the monovision and, at best, a prolonged contact lens simulation of the suggested surgical treatment.

This route maximizes significantly the number of satisfied patients after the surgery.

## Astigmatism

As discussed earlier, the surgeon attending to the needs of the lensectomy patient, whether of medical or refractive indication, needs to maintain a holistic approach to the correction of their patient's problem. The following items need to be considered to optimize the outcome for the patient:

- The removal of the opacity or error in the optical system (the cataract).
- The accurate correction of the optical state of the eye (biometry techniques and formulas, astigmatism induction avoidance, and pre-existing astigmatism correction).
- The execution of the surgery in the safest possible way in the prevailing circumstances to minimize complications (sterility, incision creation and location, wound closure, perioperative antibiotics, surgical technique, etc.) while assessing and attending to these items, ensuring that the best combination of techniques provides the optimal solution for the patient, and that includes maintaining the ability to readdress non-optimal outcomes.

The management of the astigmatism in lens surgery (or any anterior segment surgery) has become an essential and integral part of the execution of the operation.

A number of techniques have been described to control astigmatism, both in minimizing induction and treating pre-existing cylindrical error. The most useful technique that covers the most common astigmatic errors is “on-axis” incision for small-incision surgery (i.e., operative incision placement on the periphery of steep axis of the astigmatism). Other schools of thought suggest that the surgery should be performed with the smallest incision possible (astigmatically neutral), then placing the on-axis incisions in the appropriate meridian, either partial thickness (limbal relaxing incision [LRI]—vertical partial-thickness corneal incisions)<sup>44,45</sup> or penetrating (penetrating astigmatic keratotomy [PAK]—self-sealing, full-thickness, perforating incisions, obliquely orientated through the cornea). PAK is the most effective means of controlling astigmatism but does implicate corneal perforating, the mechanism of the power of the procedure. Keeping the incisions single pass and thus reducing instrument passage enhances the watertight closure, minimizes wound leak, and potentially minimizes infective risk. The power of correction in PAK can be enhanced further by creation of a second keratotomy on the opposite side of the first incision (180° opposed). The effect is greatest with penetration, reaching corrections as high as 6.00–7.00 D of astigmatism with a single pair of incisions. The PAK nomogram listed in Table 5.6.2 demonstrates the titration of the astigmatic corrective effect by variation of incision width against the optical zone radius (OZR—the proximity of the incision to the pupil/astigmatic centrum).<sup>45</sup> In the execution of cylinder correction, the patients' axes must be marked prior to lying down for anesthesia (local, topical, or general) to avoid cyclotorsional error.

TABLE 5.6.2 Penetrating Astigmatic Surgery (PAK) Nomogram

Cyl to Correct	Incision Size (mm)	Distance From Visual Axis (mm)	Opposite Incision Size (mm)	Distance From Visual Axis (mm)
1.00–1.50	3.2	6.0	nil	nil
1.50–2.00	3.2	6.0	3.2	6.0
2.00–2.50	3.5	6.0	3.5	6.0
2.50–3.00	3.5	5.5	3.5	5.5
3.00–3.50	3.5	5.0	3.5	5.0

High levels of astigmatic correction by incision as above can cause secondary higher-order aberration induction (quadrafoil). Now with the availability of a number of different toric IOLs (up to 6 D and built on an aspherical base), all providing a stable astigmatic correction, the need for high-level PAK is no longer present. It should be noted that in the selection of a toric IOL, more than one keratometric/topographic method should be used to ascertain the presence of corneal cylinder for correction. Unnecessary correction or overcorrection of cylinder should be avoided.

# The Pharmacotherapy of Cataract Surgery

5.7

Steve A. Arshinoff, Yvonne A.V. Opalinski, Dominik W. Podbielski

**Definition:** Medications used in cataract surgery.

## Key Features

- Pharmacotherapeutic agents are used in the preoperative, intraoperative, and postoperative periods of cataract surgery.
- Preoperative medications are used as mydriatics, prophylactic antibiotics, and anesthetics.
- Intraoperative pharmacotherapeutic agents include irrigating solutions and additives to irrigating solutions, as well as ophthalmic viscosurgical devices and intracameral drugs.
- Postoperative medications include antibiotics, corticosteroids, and nonsteroidal anti-inflammatory drugs.

## INTRODUCTION

With the current ongoing rapid evolution of cataract surgical techniques, corresponding changes in the pharmacotherapeutic management of cataract patients are inevitable. In this chapter, current pharmacotherapeutic practices in the pre-, intra-, and postoperative periods are reviewed.

## PREOPERATIVE MEDICATIONS

Table 5.71 provides a summary of commonly used preoperative pharmacotherapeutic routines for cataract surgery.

## Pupil Dilatation

Sympathomimetic mydriatic agents (phenylephrine 2.5%) and parasympatholytic cycloplegics (tropicamide or cyclopentolate 1.0%) usually are used together before extracapsular nuclear expression, phacoemulsification (phaco), or femtosecond laser-assisted cataract surgery (FLACS). Used excessively, sympathomimetics increase the possibility of a severe systemic hypertensive response with associated systemic risks in older adults.<sup>1</sup> For this reason, phenylephrine 10% is not recommended routinely. To assist adequate pupil dilatation, pilocarpine and other cholinergic miotics should be discontinued 12 to 24 hours before surgery (approximately twice the expected duration of action of the specific agent).

Topical nonsteroidal anti-inflammatory drugs (NSAIDs) are commonly used in cataract surgery to prevent pupillary miosis, reduce surgically induced inflammation, and prevent postoperative cystoid macular edema.<sup>2</sup> NSAIDs inhibit cyclooxygenase, decreasing prostaglandin synthesis from arachidonic acid.<sup>2,3</sup> Prostaglandin E2 (PGE2) enhances the constrictor action of the iris sphincter through a mechanism not dependent on cholinergic receptors.<sup>4,5</sup> Topical flurbiprofen 0.03%, the first agent used for this indication, was demonstrated to be clinically superior to topical indomethacin 1%.<sup>5</sup> Currently, diclofenac 0.1%, ketorolac 0.5%, and nepafenac 0.1% have the same indication.<sup>6</sup> Although diclofenac and flurbiprofen adequately maintain mydriasis during surgery,<sup>7</sup> ketorolac appears to inhibit miosis more effectively.<sup>8</sup>

Intracameral mydriatic solutions using cyclopentolate 0.1%, phenylephrine 1.5%, xylocaine 1% or tropicamide 0.5%, phenylephrine 5%, and diclofenac 0.1%, in preservative-free solutions are safe to the corneal endothelium and effective in producing and maintaining pupillary dilatation and are used in various combinations (Table 5.72).<sup>9–11</sup> Effective redilatation has also occurred with use of these mydriatics intracamerally during surgery on contracted pupils.<sup>12</sup>

**TABLE 5.7.1** Commonly Used Agents in the Routine Preoperative Pharmacotherapy of Cataract Surgery

	Class and Agent	Concentration	Dosage
Nonsteroidal anti-inflammatory drugs to prevent miosis	Diclofenac	0.10%	1 drop 2–4 times over 1 h preceding surgery
	Ketorolac	0.50%	
	Flurbiprofen	0.03%	
	Indomethacin	1%	
	Nepafenac	0.1%	
Cycloplegics	Tropicamide	1%	1 drop 2–4 times over 1 h preceding surgery
	Cyclopentolate	1%	
Mydriatics	Phenylephrine	2.50%	1 drop twice over 0.5 h preoperatively
Antibiotic prophylaxis	Gramicidin-neomycin-polymyxin B	0.025 mg/ml 2.5 mg/ml 10.000 IU/ml	1 drop 2–4 times over 1 h preceding surgery
	Gentamicin	0.30%	
	Tobramycin	0.30%	
	Ciprofloxacin	0.30%	
	Ofloxacin	0.30%	
	Gatifloxacin	0.30%	
	Moxifloxacin	0.50%	
	Trimethoprim-polymyxin B	1 mg/ml (10.000 IU/ml)	
Anesthetic: retrobulbar or parabulbar (use becoming increasingly rare)	Lidocaine	1–2%	3–9 mL
	Mepivacaine	1–2%	
	Bupivacaine	0.25–0.75%	
Anesthetic: intracameral (use becoming increasingly common)	Isotonic, nonpreserved lidocaine	1–2%	0.1–0.6 mL
Anesthetic: topical	Proparacaine	1–2%	1–2 drops prior to surgery, and then every 10 minutes or as needed during surgery
	Tetracaine	0.50%	
	Benoxinate (oxybuprocaine)	0.40%	
	Lidocaine	4%	
	Bupivacaine	0.75%	

**TABLE 5.7.2** Various Popular and Commercially Available Intracameral Mixtures to Achieve Dilatation and Anesthesia

Drug	Behndig IC Mixture (Also Made by Leiter's in USA)	Mydrane®	Xylo-Phe	Phenocaine®
Tropicamide	–	0.02%	–	–
Phenylephrine hydrochloride	1.5%	0.31%	0.08%	0.1%
Lidocaine	1.0%	1%	1%	1%

The above are various popular and commercially available intracameral mixtures to achieve dilatation and anesthesia by injecting as the first step in cataract surgery. The mixture manufactured by Leiter's Pharmacy in the USA is taken from articles by Behndig et al. from Sweden, Mydrane® is manufactured by Thea, in France, and Phenocaine® by Entod UK. Xylo-Phe has been proposed by one of the authors (SAA) to be formulated in the operating room, with details available from the author.

## Anti-infective Prophylaxis

No worldwide consensus exists on prophylactic topical antibiotics in cataract surgery, although their use has been an accepted practice for decades. A large randomized study of preoperative topical antibiotics for the prevention of endophthalmitis has yet to be carried out. The most important source of potential infectious organisms is the patient's own natural conjunctival and skin flora. Intraoperative cultures indicate that 5% of

intraocular surgeries result in measurable anterior chamber contamination from indigenous flora, but the vast majority of patients develop no adverse clinical sequelae.<sup>13</sup> Cultures from the conjunctiva and anterior chamber of patients who subsequently developed endophthalmitis usually yielded the same bacterial strains. Staphylococci (*Staphylococcus epidermidis* and *S. aureus*), diphtheroids (*Corynebacterium*), streptococci (*Streptococcus viridans*), and Gram-negative bacilli (pseudomonas, serratia, and enterobacteriaceae species, anaerobic *Propionibacterium acnes*, and others) are the most common infecting agents in decreasing order of occurrence.<sup>14–15</sup> Medications should adequately cover these bacteria during the operative and perioperative periods. Before cataract surgery, topical anti-infective regimens historically included gramicidin–neomycin–polymyxin B sulfate; aminoglycosides, such as gentamicin or tobramycin (which provide Gram-negative and pseudomonas coverage); and the fluoroquinolones—ciprofloxacin, norfloxacin, ofloxacin 0.3%<sup>7,16,17</sup> or levofloxacin 0.5%. Of these, levofloxacin provided superior coverage and anterior-chamber penetration, before fourth-generation fluoroquinolone (G4FQ) became available.<sup>18–21</sup> The G4FQs gatifloxacin 0.3% and moxifloxacin 0.5% are currently preferred because they offer better penetration compared with previous generations (moxifloxacin appears to be better than gatifloxacin),<sup>22,23</sup> broader-spectrum coverage, lower incidence of bacterial resistance, and equal safety.<sup>24–26</sup> Antibacterial prophylaxis for cataract surgery has become an increasingly prominent issue after the confirmation of increased incidence of postoperative endophthalmitis with clear corneal incisions.<sup>27</sup> Retrospective studies indicate that endophthalmitis rates are lower with the postoperative use of topical G4FQ compared with historical controls.<sup>28</sup> There have been no prospective studies determining ideal dosing for prophylactic use, but some authors have suggested that administration of antibiotics 3 days preoperatively may yield superior intraocular drug levels at surgery. A similar consensus of antibiotic use 1 to 3 days preoperatively occurred in the 2007 ASCRS member survey.<sup>27,29–32</sup> There appeared to be no difference in bacterial load with the use of moxifloxacin either 1 or 3 days preoperatively.<sup>33</sup> Several recent cases raised concerns that prophylactic use of potent antibiotics in healthy patients with cataract may lead to bacterial resistance, thereby theoretically increasing the risk of postoperative infection with a resistant strain in patients so treated. Ong-Tone<sup>34</sup> demonstrated that the aqueous concentration of antibiotics administered topically is maximal when the drops are given within 2 hours of surgery, rendering their administration days in advance unnecessary. Therefore, topical antibiotic administration every 15 minutes for three to four doses before surgery seems optimal, yielding the highest anterior chamber concentration, which permits insufficient time for resistant strains to take hold.<sup>34</sup> On a population scale, the authoritative Medical Letter has stated that the risk of causing resistant strains from the use of antibiotics in ophthalmology is minimal because of the low number of viable bacteria exposed to the agent; therefore, long-term preoperative administration of topical antibiotics may select out existing resistant strains but cannot induce new ones.<sup>35–37</sup>

Subconjunctival injections of antibiotics has been shown to reach adequate aqueous humor concentrations.<sup>38</sup> Retrospective studies have found that subconjunctival antibiotics are effective at lowering the incidence of postoperative endophthalmitis.<sup>39,40</sup>

Complete conjunctival sterility is not achievable with the use of preoperative antibiotics alone.<sup>7</sup> The topical nonselective antiseptic agent povidone-iodine 5%, instilled as a single drop 10 to 30 minutes before surgery, is one of the most effective measures to decrease this bacterial flora.<sup>41</sup> In fact, a recent prospective study found that topical moxifloxacin 0.5% lacked a significant additive effect on the preoperative reduction of conjunctival bacterial colonization beyond the effect of povidone-iodine 5%.<sup>42</sup> No consensus currently exists with regard to the use of 5% or 10% concentration of povidone-iodine.<sup>43</sup> In the event of a known or suspected iodine allergy, polyhexidine or chlorhexidine gluconate is a well-tolerated alternative, and chlorhexidine is used as a standard in Sweden instead of povidone-iodine.<sup>44</sup>

Novel approaches for prophylaxis may be on the horizon, including drug delivery nanoparticles and presoaked intraocular lenses (IOLs) with antibiotic.<sup>45</sup>

### ANESTHETICS

Anesthetics are covered in detail in Chapter 5.8. Local injection anesthesia, both retrobulbar and peribulbar, has fallen increasingly out of favor, and the use of intracameral isotonic nonpreserved lidocaine 1%, preceded by topical lidocaine, has become the standard in many centers. Lidocaine gel is claimed to provide increased corneal hydration and anesthesia equal to that of injections and drops<sup>46,47</sup> while minimizing patient discomfort, but

	Class and Agent	Concentration	Dosage
Agents added to irrigating solutions	Antibiotics		0.3–0.5 mL of 1:1000 nonpreserved epinephrine 500 mL irrigating solution
	Vancomycin plus	20 µg/mL	
	Gentamicin	8 µg/mL	
	Gentamicin	8–80 µg/mL	
	Sympathomimetics to prevent miosis		
Agents used at the end of the procedure	Nonpreserved epinephrine		0.1 mL intracapsularly via side port at end of procedure
	Antibiotics		
	Vancomycin	1 mg/0.1 mL	
	Cefuroxime	1 mg/0.1 mL	
	Cefazolin	1–2.5 mg/0.1 mL	
	Gatifloxacin	100 µg/0.1 mL	0.5 mL injected into anterior chamber via side port to cause miosis
	Moxifloxacin	100 µg/0.1 mL 100–500 µg/ 0.1–0.2 mL	
	Parasympathomimetics		
	Acetylcholine	1%	
	Carbachol	0.01%	

its popularity seems to be decreasing in favor of intracameral injection. Furthermore, presence of lidocaine gel prior to povidone-iodine instillation may reduce its antimicrobial efficacy.<sup>48</sup> Topical lidocaine 4% as the sole anesthetic agent in uncomplicated cataract surgery is also being used increasingly.<sup>49</sup>

## INTRAOPERATIVE MEDICATIONS

### Additives to Irrigating Solutions, Intracameral Antibiotics, and Other Intraocular Drugs Used During the Surgical Procedure

Table 5.7.3 gives a summary of commonly used intraoperative pharmacotherapeutic routines. In general, the addition of antibiotics, mydriatics, epinephrine (adrenaline), or lidocaine (lignocaine) is not recommended by the companies that produce irrigating solutions for cataract surgery because any effect on stabilizers and preservatives in the solutions could alter their pH, chemical balance, or osmolarity and influence the potential toxicities of both the irrigating solution and the additive. Caution is advised with any alteration to commercial irrigating solutions.

To prevent intraoperative miosis, nonpreserved epinephrine (1:1000) 0.5 mL/500 mL is the most frequently used additive. This concentration appears nontoxic to the corneal endothelium and allows normal endothelial function.<sup>50</sup>

A new U.S. Food and Drug Administration (FDA)–approved combination drug, phenylephrine 1.0%–ketorolac 0.3% (Omidria) has been studied for the treatment of intraoperative miosis and postoperative ocular pain.<sup>51</sup> The study found that this medication was better than placebo in maintaining mydriasis and preventing postoperative pain in the early postoperative period.

Insufficient evidence exists to support the addition of antibiotics into the irrigating solution, although smaller studies previously demonstrated a benefit.<sup>52</sup> Vancomycin (20 µg/mL (0.02 mg/mL)) combined with gentamicin (8 µg/mL (0.008 mg/mL)) in the irrigating solution, has been reported to eradicate Gram-positive, coagulase-negative micrococci,<sup>53</sup> with minimal associated complications.<sup>54</sup> Gentamicin alone has been used intraoperatively in the dosage range of 8 to 80 µg/mL in the irrigating solution, which avoids retinal toxicity and also decreases the intracameral bacterial load.<sup>55</sup> However, a recent large study showed no significant benefit of antibiotics added to the irrigating solution, whereas intracameral antibiotics were very effective.<sup>56</sup>

The postoperative capsular bag is a sequestered avascular site that harbors a foreign body (the intraocular lens) and may act as the nidus for most cases of endophthalmitis. Introduced by James Gills in the early 1990s, intracameral vancomycin (1 mg in 0.1 mL balanced salt solution [BSS]) was the first antibiotic agent injected directly into the capsular bag as the final surgical step. This mode of delivery is considered superior to antibiotics

added in the irrigating solution because the concentration achieved in the anterior chamber is much higher; furthermore, it is done at the end of the procedure, leaving a high dose in the anterior chamber for the early postoperative period.<sup>52,57</sup> Considerable discussion occurred among clinicians and researchers about the safety and efficacy of intracameral injections until the large, multicenter, prospective, randomized, controlled European Society of Cataract and Refractive Surgeons (ESCRS) study showed intracameral cefuroxime (1 mg in 0.1 cc, first proposed by Montan et al.) to be effective in producing an 80% reduction in endophthalmitis rates.<sup>58–61</sup> The global use of prophylactic intracameral antibiotics with cataract surgery has been steadily increasing since the ESCRS study. Dilution of cefuroxime remains a problem in the United States, but outside North America, prediluted cefuroxime is available from Thea (France) as Aprokam. However, cefuroxime does not cover multiresistant enterococci. A recent multicenter retrospective analysis of postoperative endophthalmitis in immediate sequential bilateral cataract surgery found intracameral vancomycin (1 mg in 0.1 mL) and moxifloxacin (100–500 µg in 0.1–0.2 mL) to be at least as effective as cefuroxime.<sup>56</sup> Routine use of vancomycin is controversial because it is reserved as the last resort for multiresistant bacteria. The recent discovery of 36 cases of vancomycin-associated hemorrhagic occlusive retinal vasculitis has reduced surgeons' enthusiasm about using prophylactic intracameral vancomycin.<sup>62</sup> Intracameral moxifloxacin has theoretical benefits because of its potent bactericidal activity, availability as a self-preserved commercial formulation (Vigamox®; Alcon Laboratories, Fort Worth, TX) requiring only very simple dilution, if any, and the fact that its mechanism of action differs from current antibiotics of choice for endophthalmitis, theoretically making any possible breakthrough endophthalmitis cases easily treatable.<sup>63–67</sup> Its use is steadily increasing globally. Mounting evidence supports the use of intracameral antibiotics at the conclusion of surgery because they achieve supra-threshold antibiotic levels for an extended period.<sup>60,68,69</sup>

Rapid miosis can be produced at the end of the surgical procedure by using intraocular parasympathomimetics acetylcholine chloride 1% or carbachol 0.01%.<sup>70</sup> Current commercial preparations show no evidence of endothelial toxicity, and the choice of agent depends on the desired clinical features. Acetylcholine 1% has an onset of less than 1 minute with a relatively brief 10-minute duration of miosis, whereas carbachol 0.01% takes 2 minutes to act and lasts 2 to 24 hours. Both agents lower postoperative intraocular pressure spikes.<sup>71</sup> Topical carbachol 0.2% is effective to induce 24-hour miosis and reduce postoperative IOP spikes but is no longer commercially available; therefore, pilocarpine 2% may be used, but its effect lasts only 8 hours, so the patient may be given the pilocarpine minim (in countries where minims are available; Bausch & Lomb) to reapply one drop at bedtime (personal observation – SAA).

Agents currently under investigation include low-molecular-weight heparin, enoxaparin (10 IU/mL added to standard irrigating solution), which produces a decreased inflammatory response immediately after cataract surgery with minimal side effects (e.g., hemorrhage).<sup>72,73</sup> A preliminary study of ozonated water (4 parts per million [ppm] concentration) in anterior chamber irrigation confirmed its bactericidal effects, and this may potentially be another tool against endophthalmitis.<sup>74</sup>

### Irrigating Solutions

In the early days of phaco, the only irrigating solutions available were normal saline, Plasma-Lyte, and lactated Ringer's solution. Their main adverse effect was endothelial cell toxicity. Irrigating solutions with calcium, glutathione, and bicarbonate form more physiologically balanced solutions (Table 5.7.4).<sup>75</sup> Several comparative studies found BSS Plus to be protective of the corneal endothelium and hence superior to BSS and other irrigating solutions. Unlike BSS, BSS Plus is physiologically similar to human aqueous and vitreous, especially with regard to calcium concentration and the addition of glucose, glutathione, and bicarbonate. BSS Plus maintains endothelial cell function over periods ranging from 15 minutes to in excess of a few hours.<sup>58</sup> The buffer in BSS Plus is bicarbonate, which is an improvement over the sodium acetate and citrate buffers in BSS. Nevertheless, BSS Plus is currently used much less frequently compared with BSS because of cost and the progressive reduction in the volume of irrigating fluid used in surgery as techniques improve over time.

Corneal surface irrigation to maintain hydration and surgical clarity has traditionally been performed throughout intraocular procedures with BSS. The development of an elastoviscous Hylan Surgical Shield 0.45% (HSS), which decreases the surgeon's dependence on manual corneal irrigation, is an improvement over BSS in maintaining corneal hydration and clarity intraoperatively.<sup>76</sup> Some surgeons use a drop of ophthalmic viscosurgical

device (OVD) on the cornea at the beginning of surgery to achieve prolonged wetting and reduced need for BSS irrigation with two newer topical OVDs specifically targeting this use: Visthesia (NaHa 0.3% + lidocaine 2%; Carl Zeiss Meditech) and Cornea Protect (HPMC 2%; Bausch & Lomb).

### OPHTHALMIC VISCOSURGICAL DEVICES

The introduction of Healon in 1980 for ocular surgery ushered in the era of viscosurgery. OVDs consist of solutions of long-chain biopolymers (hyaluronic acid with or without chondroitin sulfate, or only hydroxypropyl methylcellulose) in low concentration. They are all pseudoplastic in their rheological behavior. Their physical properties tend to correlate with each other (i.e., the most viscous solution is also the most elastic and the most cohesive) and are a function of the chain length distribution of the rheologically important constituent polymer and its concentration. Recently, the advent of DisCoVisc, a viscous dispersive OVD, demonstrated that the tight correlation between viscosity and cohesion in OVDs can be avoided, resulting in a new two-dimensional classification, based on zero-shear viscosity and cohesive-dispersive properties (measured as the cohesion-dispersion index [CDI]) (Table 5.7.5). OVDs cannot be correctly referred to generically, as each one has different rheological properties, and they are not generically interchangeable in that many surgical maneuvers can be achieved more easily with one type of OVD than another. Before the advent of viscoadaptive OVDs, superviscous-cohesive and viscous-cohesive OVDs were recognized as best for creating, stabilizing, and maintaining spaces (to deepen the anterior chamber in the presence of positive vitreous pressure and to stabilize the anterior chamber facilitating capsulorrhexis and foldable intraocular lens implantation). Alternatively, medium- and lower-viscosity-dispersive OVDs are excellent for the selective isolation of areas of the intraocular surgical field and for enabling fluid partition of the anterior chamber (to protect marginal corneas from the turbulence of phaco, or to keep a frayed piece of iris or bulging vitreous away from the phacoemulsifying or irrigation-aspiration tip).<sup>77</sup> Superviscous-cohesive and viscous-cohesive OVDs cannot be used to partition fluid-filled spaces. To achieve the benefits of both types of older OVDs and to avoid having to deal with their disadvantages, the “soft shell technique,” or preferably variations of the “Tri-Soft shell technique” can be utilized.<sup>78–81</sup> Healon5 and MicroVisc Phaco (iVisc Phaco, Hyvisc Phaco, BD MultiVisc) are viscoadaptive OVDs that exhibit either highly viscous-cohesive or pseudodispersive properties, depending on fluid turbulence in the anterior chamber.<sup>82</sup> The dispersive behavior of lower-viscosity OVDs and the pseudodispersive behavior of viscoadaptives are very different.<sup>82–84</sup> These characteristics allow the use of viscoadaptives for chamber partitioning and yield enhanced versatility over earlier OVDs during phaco.<sup>85–89</sup> The “ultimate soft shell technique” further enhances the scope of utility of viscoadaptive OVDs<sup>90,91</sup> and enables the benefits of the soft shell technique to be attained using a single viscoadaptive OVD. The “tri-soft shell technique” amalgamates the methodology of all preceding “soft-shell techniques” into a single systematic method,

permitting the surgeon to achieve the benefits of all soft-shell techniques in a single systematic approach. DisCoVisc is a new, viscous, dispersive OVD with zero-shear viscosity and is similar to Healon but resembles Viscoat's dispersive properties, thus permitting the chamber maintenance properties of Healon and the dispersive endothelial protection of Viscoat using a single OVD syringe.<sup>83</sup> Ophtheis FR Pro (Free Radical Protection; Rayner, UK) is another new type of OVD that possesses rheological properties similar to those of Healon but contains sorbitol, as a free-radical scavenger, with the intention of increasing endothelial protection. The advent of FLACS may revolutionize our choices and uses of OVDs because the need to stabilize and pressurize the anterior chamber for capsulorrhexis disappears. We will have to study the remaining aspects of FLACS to see what changes to OVDs will optimize surgery.

## Intracameral Medications to Replace Postoperative Drops

In the last few years, a few ophthalmologists have begun injecting an antibiotic-corticosteroid combination, Ti-Moxi (triamcinolone-moxifloxacin) or Tri-Moxi-Vanc (triamcinolone-moxifloxacin-vancomycin; Imprimis Pharmaceuticals, San Diego, CA) transzonularly as the final step in cataract surgery to avoid using postoperative topical eyedrops. Some authors have adapted this approach, and some have been very critical.<sup>92,93</sup>

## POSTOPERATIVE MEDICATIONS

Postoperative drugs are listed in Table 5.7.6.

TABLE 5.7.6 Commonly Used Agents in the Routine Postoperative Pharmacotherapy of Cataract Surgery

	Class and Agent	Concentration	Dosage
Corticosteroids	Dexamethasone	0.10%	1 drop 4 times daily for 3–4 weeks postoperatively
	Prednisolone	1%	
	Betamethasone	0.10%	
Nonsteroidal anti-inflammatory drugs	Diclofenac	0.10%	1 drop 4 times daily for 4 weeks postoperatively 1 drop 3 times daily for 2 weeks postoperatively
	Ketorolac	0.50%	
	Nepafenac	0.10%	
Antibiotics	Gramicidin-neomycin-polymyxin B	0.025 mg/mL	1 drop 4 times daily for 3–4 weeks postoperatively
	Gentamicin	2.5 mg/mL	
	Tobramycin	10 000 IU/mL	
	Ciprofloxacin	0.30%	
	Ofloxacin	0.30%	
	Gatifloxacin	0.30%	
	Moxifloxacin	0.30%	
	Trimethoprim-polymyxin B	0.30%	
		0.50%	
		1 mg/mL (10 000 IU/mL)	

## Antibiotics

Postoperative regimens of topical antibiotics vary but generally consist of one drop to the operated eye four to six times daily for 1 to 2 weeks. Recent studies support the practice of starting topical antibiotics immediately after cataract surgery, rather than waiting until the first postoperative day.<sup>94–96</sup> The duration of treatment varies from 5 days in uncomplicated surgery to weeks if prolonged inflammation occurs. Injections and collagen shields are increasingly falling out of favor.

Subconjunctival injections of antibiotics deliver high aqueous humor levels but have a greater associated risk, notably perforation of the eye, macular infarction, and retinal toxicity. Oral or parenteral antibiotics (e.g., fluoroquinolones) reach substantial levels in the anterior chamber but, being associated with increased side effects, are not advantageous over topical routes of administration.<sup>97,98</sup>

## Corticosteroids and Nonsteroidal Anti-inflammatory Drugs

The use of topical corticosteroids and NSAIDs after cataract surgery reduces postoperative noninfectious inflammation. Both are efficacious in decreasing inflammation,<sup>6,99–101</sup> with no difference between them in terms of astigmatic decay. The development of an intraocular biodegradable drug delivery system containing dexamethasone appears to be an effective alternative to topical drops,<sup>102</sup> and because a variety of drugs may be bound to the polymer matrix, it may play a role in the long-term prevention or treatment of cystoid macular edema. Topical NSAIDs have a specific advantage over corticosteroids if there are contraindications to corticosteroid use in a particular patient, as in those with corticosteroid-responsive elevations of intraocular pressure, recurrent herpes simplex infection,<sup>103</sup> or concern about delayed wound healing.<sup>104</sup> Ketorolac 0.5% has shown similar efficacy as a single agent in antimiotic and anti-inflammatory activity to an NSAID–prednisolone 1% combination.<sup>105</sup> However, an increased risk of corneal or scleral perforation in the presence of an epithelial defect exists when NSAIDs are used without concomitant administration of topical corticosteroids, most commonly reported with diclofenac.<sup>106,107</sup>

Pretreatment for 3 days with an NSAID decreases the postoperative level of inflammation.<sup>108,109</sup> Corticosteroids and NSAIDs are used postoperatively, although not as a single solution. The addition of an NSAID to an antibiotic-corticosteroid postoperative regimen reportedly has decreased the incidence of noninfectious postoperative inflammatory conditions.<sup>110</sup> The corticosteroids dexamethasone 0.1%, prednisolone 1%, and betamethasone 0.1% are used most commonly. A new corticosteroid, rimexolone 1%, seems to be similar in efficacy, with less potential intraocular pressure increase compared with either dexamethasone or prednisolone because its lipophilic nature reduces intraocular penetration.<sup>111</sup> In a recent study, a single intraoperative sub-Tenon's injection of triamcinolone (30–40 mg)<sup>112,113</sup> or intracameral triamcinolone (1.8–2.8 mg)<sup>114</sup> seemed to reduce the inflammatory response postoperatively. The most frequently used topical NSAIDs are diclofenac 0.1%, ketorolac 0.5% and, more recently, nepafenac 0.3%, and 0.1%.<sup>115–117</sup> Corticosteroid and NSAID regimens are identical and consist of one drop to the affected eye four times daily for up to 4 weeks (only once or twice daily for nepafenac), usually in conjunction with a topical antibiotic. Combination NSAID–antibiotic drops have been formulated to minimize the number of different bottles a patient must use postoperatively, without altering either the drug's efficacy or penetration.<sup>118</sup>

## LATE POSTOPERATIVE MEDICATIONS

### Treatment of Endophthalmitis

Endophthalmitis has been treated with antibiotics systemically, intravitreally, and topically. See Chapter 79 for details.

### Treatment of Cystoid Macular Edema

Cystoid macular edema (CME) usually manifests 1 to 3 months postoperatively as either decreased visual acuity or changes on fluorescein angiography or optical coherence tomography (OCT) resulting from serous exudate leaking from incompetent intraretinal capillaries into the outer plexiform

layer of Henle.<sup>119</sup> Most patients recover spontaneously, with full restoration of visual acuity within 6 months; however, it may require 1 to 2 years to achieve complete spontaneous resolution.<sup>2</sup>

Prophylaxis and treatment have been suggested in the form of systemic and topical NSAIDs. Oral NSAIDs, with regimens of indomethacin 25 mg three times daily 1 week before surgery and 3 weeks postoperatively,<sup>2</sup> or ibuprofen 200 mg preoperatively and postoperatively, have received mixed reviews.<sup>120</sup> Literature supports the efficacy of topical NSAIDs,<sup>121–123</sup> such as flurbiprofen 0.03%, diclofenac 0.1%, ketorolac 0.5%, bromfenac 0.09%, and nepafenac 0.1% used prophylactically and after surgery to reduce inflammation.<sup>124,125</sup> Piroxicam 0.5% solution used postoperatively appears as effective as diclofenac, with less ocular irritation.<sup>126</sup> The prodrug Nepafenac 0.1% has shown significantly greater ocular bioavailability and potency compared with ketorolac 0.4% and bromfenac 0.09%.<sup>125</sup> Usually, preoperatively and postoperatively, one drop is administered two to four times daily for up to 3 weeks to prevent CME. Frequently, in the acute postoperative period, topical corticosteroids used in conjunction with NSAIDs in the treatment of CME<sup>127</sup> produce a synergistic effect.<sup>128</sup> Recent evidence also suggests that solitary topical NSAID treatment is superior to lone corticosteroid prophylaxis.<sup>129–132</sup> In chronic cases, management continues until resolution.<sup>2</sup> Indefinite NSAID treatment may be required to maintain CME regression,<sup>133</sup> which increases interest in the utility of a sustained drug delivery system, such as Ozurdex.<sup>134</sup> Once it has been established, CME is treated with oral acetazolamide, topical corticosteroids with NSAIDs, or posterior sub-Tenon's injection of long-acting corticosteroids (see Chapter 6.35). Single-dose intracameral, intraoperative, and multiple intravitreal postoperative injections of triamcinolone also have safely prompted regression of chronic CME with minimal changes in intraocular pressure.<sup>99,135–137</sup> Oral cyclooxygenase-2-inhibitors were found to successfully resolve CME unresponsive to oral or topical NSAIDs in a small number of patients, with improvement in visual acuity,<sup>138</sup> as has high-dose methylprednisolone (1000 mg for 3 days)<sup>139</sup> in the past. Recent case series investigations suggest anti-vascular endothelial growth factor (VEGF) as an alternative for recalcitrant CME, but large controlled trials are lacking.<sup>140–143</sup> Oral carbonic anhydrase inhibitors (CAIs) may be effective in treating refractory CME, but their use is guarded because of severe adverse effects.<sup>144</sup> Antiglaucomatous prostaglandin analogues may enhance disruption of the blood–aqueous barrier, increasing the incidence of CME after cataract surgery, but this appears to be a response to the drug's preservative, and not the drug itself. The concurrent application of NSAIDs decreases the incidence of CME secondary to these medications and does not adversely influence the anti-glaucoma drug's effect on intraocular pressure.<sup>145,146</sup>

# Anesthesia for Cataract Surgery

Keith G. Allman

# 5.8

**Definition:** Procedures and medications given to allow successful completion of lens removal with minimal risk, pain, and anxiety.

## Key Features

- Consideration of patient characteristics.
- Local anesthesia: considerations, sedatives used, local anesthetics used.
- Local techniques: topical, retrobulbar—advantages, disadvantages; peribulbar and sub-Tenon's—comparison.
- General anesthesia: techniques, advantages, disadvantages, and complications.

## INTRODUCTION

The advent of small, self-sealing cataract incisions has allowed a change in the practice of anesthesia for cataract surgery. Local and topical techniques are now the norm, with less than 2% of patients requiring general anesthesia.<sup>1</sup> However, anesthesiology input remains important, as even topical techniques have been shown to require anesthesiologist intervention for 22%–28% of cases.<sup>2,3</sup>

A team approach is important because it allows the surgeon to concentrate on the operation while the anesthesiologist cares for the patient.<sup>4</sup>

## MEDICAL ASPECTS OF ANESTHESIA FOR CATARACT SURGERY

### Cataract Type and Associated Medical Conditions

Cataracts can be either congenital or acquired and may be an ocular manifestation of a systemic disease. Younger patients may have uncommon medical conditions, whereas those with acquired cataracts are usually older (average age 75 years) and have comorbidities, such as ischemic heart disease and chronic obstructive airway disease. In an audit of 1000 cases in Auckland, 43% were identified as American Society of Anesthesiologists (ASA) grades 3–4.<sup>5</sup> There is also a significant increase in overall mortality in those with concurrent hypertension (48%), ischemic heart disease (38%), and diabetes (16%).<sup>6</sup>

Routine preoperative investigations, however, are not usually indicated, with the exception of testing for clotting in some patients taking oral anticoagulants, for electrolytes in those having dialysis, and for blood sugar in those with a history of diabetes.<sup>7,8</sup> An assessment of the patient's ability to lie flat and still is important.

### Specific Conditions

#### Ischemic Heart Disease

Ischemia can be provoked by stress and anxiety at the prospect of surgery and anesthesia. If possible, surgery should be avoided for 3 months after myocardial infarction, angioplasty, or coronary revascularization. Phenylephrine drops may result in a significant rise in blood pressure and should be limited to a 2.5% solution. The oxidative damage resulting in cataract formation is linked to free radical formation and atherosclerosis, which

explains the high proportion of patients with coexisting ischemic heart disease.<sup>6</sup>

### Anticoagulants

Patients on oral anticoagulants and antiplatelet therapy, including aspirin and clopidogrel, should continue with these throughout surgery.<sup>9–12</sup> The risks of cardiovascular complications if these agents are stopped outweigh the potential risks of hemorrhage. General anesthesia, sub-Tenon's block, or topical local anesthesia is recommended.

### Diabetes Mellitus

Local anesthesia causes the least disruption to diabetic management and is preferred.<sup>13</sup> Normally, patients do not need to fast (see below).

## LOCAL ANESTHESIA

Local anesthesia can be classified into topical, retrobulbar, peribulbar, and sub-Tenon's block.

### General Considerations

The main advantage of local anesthesia is minimal disruption for the patient. Sedation may be useful, particularly in the anxious.<sup>14</sup> Patients given local anesthesia without sedation or with “minimal” sedation (as defined by the ASA) need not be starved.<sup>15,16</sup> Guidelines for standard fasting times should be followed for deeper sedation or general anesthesia.<sup>16</sup>

Minimal monitoring should include electrocardiography (ECG) and pulse oximetry. Older adults and those with systemic illnesses should be anesthetized in an appropriate environment with backup facilities if inpatient or critical care is required.<sup>17</sup> Supplemental oxygen is given to avoid hypoxia and to minimize claustrophobia. Rebreathing can occur under the drapes even at 6 L/min of oxygen.

Nonmedical personnel often perform an assessment prior to surgery. Accurate listing for local or general anesthesia can be a problem because many patients have comorbidities. A questionnaire filled in by patients has been shown to be a good initial screening tool, with supplemental medical input as required.<sup>14</sup>

Many patients have visual experiences under local anesthesia; in one survey 16% found this distressing.<sup>18</sup> Counseling preoperatively has been shown to be beneficial in reducing this distress.<sup>19,20</sup>

All operating room personnel must be trained in basic life support, and at least one member should have advanced training. The Joint Royal Colleges in the United Kingdom recommend that an anesthetist be present throughout, whether general or local anesthesia is used, and this is essential if sharp needle technique or sedation is contemplated. For patients undergoing topical anesthesia or sub-Tenon's block, an anesthetist does not need to be present, unless the site is isolated.<sup>8,17</sup>

There are few absolute contraindications to local anesthesia, but patient refusal and the possibility of noncooperation during surgery remain the commonest.

### Topical Anesthesia (see Box 5.8.1)

More than 60% of all cataract operations are performed with the patient under topical anesthesia in the United States and around 33% in the United Kingdom.<sup>21</sup> Oxybuprocaine (benoxinate) 0.4%, an ester anesthetic,

### BOX 5.8.1 Advantages and Disadvantages of Topical Anesthesia

#### Advantages

- No risk associated with needle insertion
- Reduced risk of periocular hemorrhage
- Functional vision is maintained; advantageous for unioocular patients
- Reduced postoperative diplopia and ptosis

#### Disadvantages

- An awake and talkative patient can be distracting for the surgeon
- No akinesia of the eye
- Less effective anesthesia compared with sub-Tenon's block
- Increased risk of surgical complications; if difficulties or problems occur, anesthesia may be inadequate
- May be unsuitable for less experienced surgeons

#### Adverse Effects of Topical Ocular Anesthetics

- Direct corneal effects—alteration of lacrimation and tear film stability
- Epithelial toxicity—healing has been shown to be delayed when an epithelial defect occurs (lidocaine does not appear to affect healing)
- Endothelial toxicity—this occurs when penetrating trauma is present and appears to be related to the preservative benzalkonium
- Systemic effects—lethal toxicity (this is only a problem with cocaine)
- Allergy and idiosyncratic reactions

#### Secondary Adverse Effects

- Surface keratopathy

### BOX 5.8.2 Advantages and Disadvantages of Retrobulbar Block

#### Advantages

- Reliable akinesia
- Onset of block is quicker than with peribulbar anesthesia
- Low volumes of anesthetic result in a lower intraorbital tension and less chemosis than with peribulbar blocks
- Temporary loss of visual acuity occurs more reliably than for peribulbar block

#### Disadvantages

- Risk of brainstem anesthesia—reason for the development of the peribulbar block
- Risk of myotoxicity and globe perforation

is frequently used. Proparacaine (proxymetacaine) 0.5% is less toxic to the corneal epithelium, does not sting on application, but has a shorter duration of action (20 minutes). Other agents, including tetracaine (ame-thocaine) 0.5%–1%, lidocaine 1%–4%, and bupivacaine 0.5%–0.75%, have longer durations of action but increased corneal toxicity and pain on application.

Topical anesthesia may be combined with subconjunctival or, more commonly, intracameral anesthesia to improve patient comfort. Preservative-free lidocaine 1% 0.3–0.5 mL appears to be effective and safe.<sup>21,22</sup>

As visual perception is not lost, the patient is asked to focus on a light, the intensity of which is reduced. Subconjunctival injection of antibiotics can be painful and can be avoided by intracameral administration.

Use of topical anesthesia has been increasing throughout the United States and Europe despite several studies demonstrating inferior analgesia compared with both peribulbar and sub-Tenon's blocks and a possible increase in surgical complication rate (4.3% posterior capsular tear for topical compared with 2.1% for sub-Tenon's anesthesia).<sup>4,23–25</sup>

With correct selection of patients and surgery performed by experienced surgeons, many centers have shown good results, but because there is no akinesia of the eye, it may not be suitable for inexperienced surgeons or uncooperative patients.<sup>26</sup>

### Retrobulbar Block (see Box 5.8.2)

With this technique, the aim is to block the oculomotor nerves before they enter the four rectus muscles by depositing the local anesthetic directly into the posterior intraconal space (Fig. 5.8.1). Although the resultant akinesia is usually profound, serious complications, such as brainstem anesthesia, globe perforation, and myotoxicity, have rendered the technique

#### ADVANCEMENT OF NEEDLE IN RETROBULBAR BLOCK

Fig. 5.8.1 Advancement of needle in retrobulbar block.

TABLE 5.8.1 Comparison of Peribulbar and Sub-Tenon's Block

Peribulbar Block	Sub-Tenon's Block
More pronounced akinesia	Less akinesia
Lower rates of chemosis and subconjunctival hemorrhage	High rates of chemosis and subconjunctival hemorrhage
Risk of globe perforation, retrobulbar hemorrhage, myotoxicity	Complications rarely serious
Small risk of brainstem anesthesia	Improved analgesia
	Lower dose and volume of anesthetic agent are used
	Less painful to perform

relatively obsolete. For sharp needle anesthesia, peribulbar block offers a safer, equally effective method.<sup>27,28</sup>

### Peribulbar Block (see also Table 5.8.1)

The principle of this technique is to instill the local anesthetic outside the posterior muscle cone and thereby avoid accidental injection into the optic nerve (which would cause brainstem anesthesia). This utilizes higher volumes (6–10 mL) of the local anesthetic compared with the traditional retrobulbar block, and the application of a pressure device is often needed.

#### Technique

With the eye in primary gaze, local anesthetic drops are applied to the cornea. At the inferotemporal lower orbital margin, a 25-gauge, 25-mm needle is advanced parallel to the plane of the orbital floor either transcutaneously or transconjunctivally. A degree of upward and inward angulation may be needed once the needle goes past the equator of the globe. Local anesthetic (4–6 mL) is injected at a depth of about 20 mm from the inferior orbital rim (in an eye of normal axial length). No resistance to injection should be felt, and prior aspiration should be performed (Fig. 5.8.2 and Fig. 5.8.3).

After 5 minutes, the degree of akinesia is assessed. If a second medio-canal injection is required, a 25-gauge, 25-mm needle is inserted between the medial canthus and the caruncle and directed immediately backward. The medial check ligament is often penetrated. At a depth of 15 mm, after prior aspiration, another 4–6 mL of solution is injected to produce a more complete block, with akinesia of the orbicularis oculi and levator palpebrae superioris. A Honan balloon or pressure-lowering device is often applied for 5–10 minutes.

Peribulbar block has been reported to be more painful than using topical anesthesia.<sup>29,30</sup> It is important that adequate training be given to decrease complications from the use of all of these blocks.

#### Local Anesthetic Agent

The most common agent used is lidocaine 2% plus hyaluronidase 15 IU/mL. If greater duration of anesthesia is required, the lidocaine can be mixed in a ratio of 50:50 with bupivacaine 0.5%.

Other agents used include 2-chloroprocaine 2%–3%, mepivacaine 1%–2%, bupivacaine 0.25%–0.75%, prilocaine 3%, and ropivacaine 0.75%.<sup>31</sup> Levobupivacaine is the L-isomer of bupivacaine with a higher safety index, especially in terms of cardiac toxicity. Articaine 2%–4% is an amide local

**Fig. 5.8.2** Inferotemporal peribulbar injection. (A) The needle enters the orbit at the junction of its floor with the lateral wall, very close to the bony rim. (B) The needle passes backward in a sagittal plane parallel to the orbit floor. (C) It passes the globe equator when the needle-hub junction reaches the plane of the iris. (D) After test aspiration, up to 10 mL anesthetic solution is injected. (Adapted from Hamilton RC. Techniques of orbital regional anaesthesia. *Br J Anaesth* 2001;86:473–6.)

**Fig. 5.8.3** Transconjunctival peribulbar injection technique.

anesthetic of low toxicity used predominantly in dentistry. Because of its rapid onset, short duration of action, low toxicity, and better penetration of tissues, it has been shown to produce good quality blocks.<sup>32–36</sup>

Epinephrine 5 µg/mL is sometimes added to improve onset time, quality, and duration of the block. However, it should be avoided in older patients with atherosclerosis and has been implicated in optic artery thrombosis secondary to vasoconstriction. A 50% decrease in pressure in the ophthalmic artery has also been noted.

Hyaluronidase is an enzyme derived from the testicles of rams (previously from the testicles of cattle), although a recombinant version is now available. It hydrolyzes C1–C4 bonds between glucosamine and glucuronic acid in connective tissue, thus enabling the local anesthetic to penetrate tissues more effectively. The required quantity of the local anesthetic, therefore, is reduced, and the time to onset decreased. Hyaluronidase may also help prevent damage to the extraocular muscles, especially the inferior rectus muscle, preventing diplopia.<sup>37</sup>

### Complications

Most serious complications of peribulbar anesthesia are associated with the use of sharp needles.

- **Globe perforation/penetration.** Incidence 1.4–1.9 per 10 000.<sup>38–40</sup> More common in high myopes (>26 mm axial length) and with inexperience. Usually results in marked visual loss because of permanent retinal damage.
- **Retrobulbar hemorrhage.** Incidence 0.6–4.2 per 10 000.<sup>38–40</sup> More common in those taking anticoagulants. May require surgical decompression.
- **Extraocular myotoxicity.** Incidence 25–100 per 10 000.<sup>41,42</sup> Related to inadvertent direct injection of the local anesthetic into the muscle

belly. Myocyte cell death is followed by hypertrophic regeneration and shortening.<sup>43,44</sup>

These serious complications have led some authorities to recommend abandoning sharp needle techniques altogether.<sup>42</sup> The UK Royal College of Ophthalmologists has also stated:

“Sharp needle local anaesthetic techniques have a higher risk of ocular and systemic complications than sub-Tenon’s or topical techniques and should only be used when the anaesthetist and surgeon consider it absolutely necessary.”<sup>45</sup>

In 2017 the UK National Institute for Health and Care Excellence (NICE) concluded that peribulbar anesthesia should no longer be used for routine cataract surgery where Topical or sub-Tenon’s anesthesia is possible.<sup>46</sup>

Certainly, sharp needle blocks are responsible for the majority of ophthalmic anesthesia-related problems and are the most common cause of regional anesthesia-related litigation after centroneuraxial blockade in the United Kingdom (average settlement £24 000).<sup>47,48</sup>

### Sub-Tenon’s Block (see also Table 5.8.1)

This was first described by Turnbull in 1884 when he used open dissection of Tenon’s layer followed by instillation of cocaine. Later modifications were introduced by Stevens, Greenbaum and Allman.<sup>49–53</sup>

Sub-Tenon’s block involves surface anesthesia and surgical access to sub-Tenon’s space. In the United Kingdom, this now is the most common method used in cataract surgery, comprising 47% of cases.<sup>54</sup>

### Anatomy

This is described in more detail elsewhere in this text. Briefly, Tenon’s capsule (after Jacques René Tenon [1724–1816], French anatomist/surgeon) is a facial sheath, a thin membrane enveloping the eyeball and separating it from orbital fat. The inner surface is smooth and shiny, separated from the outer surface of the sclera by a potential space, the episcleral or sub-Tenon’s space. Anteriorly, the capsule fuses with conjunctiva 5–10 mm from the limbus. Posteriorly, it fuses with the meninges around the optic nerve. It has been suggested that it is a lymph space and is crossed by numerous delicate bands.

### Technique

The conjunctiva is anesthetized first with a topical local anesthetic of choice. The most common approach is via the infranasal quadrant because this allows for good distribution of the anesthetic while decreasing the risk of damage to the vortex veins. The eye is cleaned with 5% iodine, and the patient is asked to look upward and outward. Aseptically, the conjunctiva and Tenon’s capsule are held 3–5 mm from the limbus using nontoothed Moorfield’s forceps (Fig. 5.8.4).<sup>52</sup> A small incision is made through these layers using blunt-tipped, sprung Westcott scissors, exposing the sclera. A cannula is then advanced into the sub-Tenon’s space and around the globe.

Sub-Tenon’s anesthesia can be broadly divided into anterior and posterior techniques. In the former, the cannula tip remains anterior to the

**Fig. 5.8.4** Incision for sub-Tenon's block. Arrows point to conjunctiva, Tenon's capsule, and shining sclera under the Tenon's capsule. (Reprinted with kind permission from Kumar CM, Williamson S, Manickham B. A review of sub-Tenon's block: current practice and recent development. *Eur J Anaesthesiol* 2005;22:567–7, Figure 2c, European Academy of Anaesthesiology, published by Cambridge University Press.)

globe equator. This reduces the risk of inadvertent misplacement but increases the rate of chemosis and can make akinesia difficult to achieve. For more profound akinesia, the cannula tip should be placed posterior to the equator but must be positioned with care, gently following the curve of the globe (Video 5.8.1).

See clip:  
5.8.1

Numerous cannulae have been described.<sup>55</sup> The plastic Greenbaum cannula (12-mm 15-gauge) is suitable for anterior blocks, whereas a metal Stevens cannula (25-mm 19-gauge) is most suitable for posterior techniques (Fig. 5.8.5).

An alternative technique that requires no prior conjunctival incision uses a pencil-point cannula (25-mm 21-gauge Triport cannula; Eagle Laboratories).<sup>55</sup> This reduces the amount of conjunctival damage and decreases reflux of the local anesthetic. The blunt cannula entry site leaves a very small, self-sealing wound, which then heals rapidly with less conjunctival scarring compared with traditional techniques (Video 5.8.2).

See clip:  
5.8.2

The sub-Tenon's (or episcleral) space also can be accessed using a “B” beveled needle, as described by Jacques Ripart.<sup>56</sup> Although a useful and reliable technique, this somewhat negates the advantages of using a blunt cannula.

The local anesthetic in a dose of 3 to 5 mL is injected; the greater the volume, the greater is the degree of akinesia. Lidocaine 2% is usually used in combination with hyaluronidase. Addition of hyaluronidase reduces the median effective volume (EV50) needed from 6.4 to 2.6 mL.<sup>57</sup> Articaine 2%–4% may be even more effective.<sup>36</sup>

A Honan's balloon can be used to increase dispersal; however, it is not usually needed.

Complications are mainly minor (chemosis and subconjunctival hemorrhage), although orbital inflammation, scleral perforation, cardiovascular collapse, and sight-threatening and life-threatening complications have all been reported.<sup>58–61</sup>

## SEDATIVE AGENTS

Sedation is a useful adjunct to local anesthesia for many patients—particularly those who are unduly anxious.

Midazolam, a short-acting, water-soluble benzodiazepine with a half-life of 2 hours, has both amnesic and anxiolytic properties, lacks venous sequelae, and allows rapid patient recovery. It is given intravenously in 0.5- to 1-mg increments. Adequate time between doses must be allowed in older adults, or oversedation could result. Overdoses can be reversed with flumazenil, a specific benzodiazepine antagonist, but its half-life is 1 hour, so resedation can occur.

Propofol, a short-acting phenol, is an intravenous induction agent suitable for infusion and sedation. It is characterized by the patient's rapid and clear-headed recovery and is associated with a low incidence of nausea and vomiting. It causes respiratory depression and a fall in blood pressure.

Propofol and midazolam have both been used for patient-controlled sedation.<sup>62</sup>

**Fig. 5.8.5** Three cannulae used for sub-Tenon's anesthesia. (A) Greenbaum cannula 15-gauge 12-mm. *Middle*, Triport cannula (Eagle Laboratories) 21-gauge 25-mm. (B) Steven's cannula (Visitec) 19-gauge 25-mm.

### BOX 5.8.3 Advantages and Disadvantages of General Anesthesia

#### Advantages

- Patient comfort
- Ideal operating conditions—a quiet, immobile patient and soft eye
- Allows for rapid alterations in intraocular pressure, if required
- No risk of complications associated with local anesthetic blocks
- No residual paralysis of the eye when the patient is awake
- Bilateral surgery can be performed
- Better conditions for teaching

#### Disadvantages

- Slower turnaround times
- More expensive
- Greater risk in frail older adults
- Greater physiological disruption for patient

Fentanyl is a potent, short-acting narcotic analgesic with a duration of action of about 30 minutes. Given in doses of 25–50 µg, it provides analgesia with minimal sedation and is a useful adjunct to midazolam or propofol. Side effects include respiratory depression, nausea, and vomiting.

Remifentanyl is a potent, ultra-short-acting alternative but can cause a marked fall in heart rate and blood pressure in older adults.

Dexmedetomidine, an  $\alpha_2$  agonist, has also been used as a sedative agent with good effect.<sup>63</sup>

## GENERAL ANESTHESIA

General anesthesia is useful in those patients unsuitable for local anesthesia; it is the method of choice for babies, children, and the uncooperative (see Box 5.8.3).<sup>64</sup>

In the past, it was necessary to intubate, paralyze, and ventilate the patient. However, with the advent of phacoemulsification (“phaco”) and

small incision surgery, plus the use of propofol with a laryngeal mask airway, it is now feasible to have the patient breathing spontaneously. Avoiding intubation allows for the use of a lighter anesthetic, decreases cardiovascular depression, and improves recovery. In patients 80 years of age or older, psychomotor testing has shown that total intravenous anesthesia with propofol and remifentanyl results in significantly faster recovery of cognitive function compared with etomidate–fentanyl–isoflurane.<sup>65</sup>

A recent study that compared balanced anesthesia with total intravenous anesthesia (TIVA) showed similar cardiovascular effects but decreased nausea and vomiting, faster recovery, better patient satisfaction, and lower costs with TIVA.<sup>66,67</sup>

## Technique

### Spontaneous Respiration

A laryngeal mask is inserted, and anesthesia is maintained with either a continuous propofol infusion or a volatile agent of choice. Target-controlled infusion regimens are commonly employed. Propofol 4.5 µg/mL bolus for induction followed by 3.26 µg/mL maintenance target infusion levels can be combined with either an alfentanil (target blood concentration 25 ng/mL) or remifentanyl (target blood concentration 1–1.5 ng/mL) infusion, although propofol plus topical anesthesia is usually sufficient. The use of a laryngeal mask enables faster turnaround times and reduces the cough associated with extubation. It provides a stable, easily controlled anesthetic, resulting in rapid recovery and a low incidence of nausea and vomiting.

### Ventilation

The traditional method involves endotracheal intubation, although controlled ventilation is possible with a laryngeal mask. This combines the benefits of avoiding intubation and causing paralysis in the patient. Suxamethonium is avoided, if possible, because a transient rise in intraocular pressure occurs with its use. Short-acting nondepolarizing blockers are preferred. Maintenance consists of using a volatile agent or a propofol infusion. Although patient throughput may be slower, this technique provides stable, well-controlled anesthesia and is the method of choice for certain patients in whom spontaneous respiration would be inappropriate (e.g., obese individuals).

### Conclusions

Both spontaneous respiration and ventilation methods are suitable for day-case anesthesia. They are both widely used in all other specialties. Both propofol and the newer volatile agents sevoflurane and desflurane provide a particularly rapid and clear-headed recovery.

Hypotension needs to be aggressively treated with vasoconstrictors, such as ephedrine or metaraminol, to minimize morbidity.

## POSTOPERATIVE CARE

Cataract extraction by phaco is relatively pain-free. In the majority of cases, simple oral analgesics are sufficient. Nonsteroidal anti-inflammatory drugs should be used with caution in older adults. Topical nonsteroidal analgesics can decrease pain and inflammation<sup>68</sup> and have been shown to be equally effective in reducing the inflammatory response compared with corticosteroids, with fewer side effects. Corticosteroids should be reserved for cases with more severe inflammation.<sup>69</sup> Topical local anesthesia can also be used as an adjunct, as it reduces systemic anesthetic requirements. This may reduce postoperative nausea and vomiting by avoiding the use of opiates. Propofol also has antiemetic properties.

# Phacoemulsification

David Allen

## 5.9

**Definition:** A surgical technique to remove the nuclear portion of a cataractous lens using an aspirating and vibrating ultrasonic handpiece.

### Key Features

- Changing phacoemulsification (“phaco”) “power” or “amplitude” is achieved by changing the stroke length of needle vibration, not by changing the frequency.
- Evidence is accumulating that direct mechanical action is the most important factor in phaco.
- Power modulation significantly increases the efficiency of longitudinal phaco as well as improving the thermal safety. It is less important with torsional phaco.
- Modern pump systems are efficient and high vacuums can be achieved very quickly with modern flow-based (peristaltic) systems.
- In a flow-based machine, the aspiration flow rate can be adjusted completely independently of the preset vacuum limit.
- In a vacuum-based (Venturi) machine, the aspiration flow rate is generated by the pressure difference between the vacuum chamber and the eye. In most machines, the two cannot be completely dissociated, and a high vacuum results in higher flow rates compared with a lower vacuum.
- Modern machines feature a variety of strategies to minimize postocclusion surge. Postocclusion surge potential is directly related to the maximum set vacuum for any given needle/sleeve/tubing complex.

### INTRODUCTION

As surgical techniques for the removal of cataract along with drug modulation of the consequent biological responses have become more refined, the problems of postoperative infection and inflammation are less important concerns of lens surgeons. As a consequence, it has become possible to concentrate on the further refinement of the actual process of lens removal. Phacoemulsification (“phaco”) offers the surgeon the possibility to break the nucleus into smaller pieces and even into a fine emulsion of material, all of which can be removed through the probe used to achieve the breakup. As a result, it is now possible to minimize trauma to the structures of the eye and to have minimal impact on its shape as a consequence of modern cataract surgery. Achieving this, however, requires the use of very powerful tools. Unfortunately, many surgeons fail to understand the principles that underlie the machines they use. As a consequence of this relative ignorance, surgery is sometimes performed less efficiently and possibly more dangerously than necessary.

### HANDPIECES AND TIPS

The phaco handpiece houses an ultrasonic transducer—a device that converts electrical energy into mechanical vibratory energy. Standard handpieces couple the crystal to the phaco tip in such a way that the tip moves backward and forward when the crystals deform. In 2006, Alcon Surgical (Fort Worth, TX) introduced a handpiece (OZil) that can cause the tip to tort or twist when the crystals deform. It is constructed in such a way that when oscillating at 32 kHz the crystals produce torsion, and when stimulated at 44 kHz, they produce traditional linear movement. If a tip with a

bend in the shaft (Kelman tip) is attached to such a handpiece, then the twisting of the shaft is converted into a sweeping side-to-side motion at the end of the tip. Following this, Abbot Medical Optics (AMO, Santa Ana, CA) introduced a third modality whereby with their new handpiece (Ellips FX), the phaco needle is made to traverse laterally while it moves forward, taking what they call an *elliptical path*.

The frequency at which a handpiece is set to work depends on the design and materials used. Adjustment of the power setting on the machine affects the stroke length (the distance traveled by the tip during one cycle), but not the frequency. Power is expressed as a percentage of the maximum travel the crystal-tip complex can produce. It is clear that if the frequency remains constant but the distance traveled in each stroke increases, the acceleration of the tip and the maximum speed it reaches must be greater. It is important to recognize that the power settings on the machine console are indicative only. Some systems have a nonlinear relation between commanded power and stroke length. The smallest stroke (at minimum power setting) also varies among systems. In one commercially available system, 20% power produces tip travel of 50  $\mu\text{m}$ , whereas this travel is reached only at 60% power in another machine. As a consequence, any comparisons between the “efficiency” of different phaco machines based on comparisons of “power used” are spurious.

The physical mechanisms that break up nuclear material when a phaco tip is used have been difficult to elucidate, and the relative importance of the various factors is still unclear.<sup>1,2</sup> For example, a phaco tip operated at a frequency of 44 kHz has a maximum speed of 66 ft/second (20 m/second) when operated at full power, and the acceleration of the tip is >168 300 ft/second (>51 000 m/second). Under these conditions, the direct impact of the tip breaks the frictional forces within the nuclear material. This direct effect is reduced, however, by the forward-propagating acoustic waves or fluid and particle waves generated by the tip, which tend to push away any piece of nucleus in contact with the tip. However, some still postulate that the acoustic shock waves themselves tend to weaken or break some of the bonds that hold nuclear material together. The role of cavitation in breaking down lens material remains controversial, but some evidence exists that it is not required for effective phaco.<sup>3</sup>

Various tip designs are available for the surgeon, but there are three key design variations, and each of the tip designs usually is available with a “cutting tip” angle of 30° or 45°. The tip may be straight with a uniform diameter along its length. The Kelman tip has a 22° angle in the shaft 3.5 mm from the tip. This design is thought to enhance the emulsification action of the tip, as well as allowing the surgeon to use it as a manipulator. Some tips have a flared termination of the tip (i.e., the outer and inner diameter at the end of the tip is greater than that 1–2 mm behind). While the larger mouth creates more holding force, the restriction of the inner lumen behind the flare helps suppress postocclusion surge. More recently, a completely new tip design has been introduced. When torsional phaco was developed, the already available Kelman design tip was used. It seemed logical that rotating the shaft along its long axis would result in a sweeping side-to-side action at the tip end. Although this proved to be the case, it was later realized that there was not just simple rotation of the shaft with this design. This realization resulted in a completely new tip shape, specifically designed for torsional phaco (the “balanced” tip) (Fig. 5.9.1). By significantly reducing the unwanted movement in the shaft, more of the energy produced by the ultrasound crystals is translated into sweeping movement at the very end of the tip, giving a stroke length of 190  $\mu\text{m}$  at maximum amplitude compared to 130  $\mu\text{m}$  with the Kelman tip.<sup>4</sup>

**Fig. 5.9.1** The balanced tip developed specifically for torsional phaco. (Courtesy Alcon Surgical.)

## POWER MODULATION

Although some form of simple power modulation (pulsed phaco) has been available for a long time, the introduction in 2001 of the Whitestar software for the AMO Sovereign phaco machine marked a paradigm shift in the way surgeons controlled the application of phaco power. Breakup of phaco into pulses or bursts has two advantages. First, the pauses (off-period) allow the machine fluidics to pull material back into contact with the tip following repulsion caused by the jack-hammer effect in traditional longitudinal phaco. Second, the pauses prevent significant buildup of heat as a result of frictional movement within the incision, making thermal damage to the cornea less likely. Several machines now allow almost infinite variation of both duty cycle (the ratio of on-time to off-time) and the length of the on-period. It has been shown that such power modulation significantly improves the “efficiency” of phacoemulsification (i.e., quicker surgery and reduced amount of phaco energy used).<sup>5</sup> With the introduction of torsional phaco the reduced repulsion and reduced thermal effect mean that power modulation is less important, although many surgeons continue to apply modulations.

When first introduced, pulses had a fixed duty cycle of 50% (i.e., the period with power on and with power off were equal), but power was variable, whereas bursts were of fixed width, usually with fixed power also. First Bausch & Lomb (Bridgewater, NJ) and now most other manufacturers have enhanced the various possible combinations of modulation, and this distinction has become blurred and is probably no longer helpful to try to distinguish between them in advanced machines.

## PUMPS AND FLUIDICS

The function of the phaco pump is twofold—to hold the nucleus onto the tip and to remove debris created by the tip. With modern techniques the pump also is used increasingly to aspirate directly the softer parts of the nucleus. There are two pump principles in general use—flow-driven and vacuum-driven. Some machines now have the ability to switch between the two modes during surgery.

### Flow-Based (Peristaltic)

Roller pumps that rotate against compressible tubing or membrane generate flow; this “milks” fluid along the lumen and creates a pressure gradient between pump and anterior chamber (AC). Recent design changes in the pumps and sophisticated microprocessor controls have resulted in powerful and well-controlled pump systems. The rate at which fluid is aspirated through the unoccluded phaco tip is set at the machine console in milliliters per minute (mL/min). A low value allows events within the AC to happen slowly; a high value speeds up events and generates more “pulling power.” Fine adjustments of flow, achieved by changing the speed at which the pump turns, allow for personal surgical style or different operating conditions. Recent advanced systems sense when the tip is occluded partially and then make adjustments to the pump to compensate for reduced aspiration.

The second pump parameter that can be adjusted is the vacuum level at which, once achieved, the pump stops. When the tip becomes occluded, the pump continues to turn and move fluid into the cassette, increasing the vacuum level in the tubing between tip and cassette. Once the preset vacuum has been reached, the pump effectively stops (or turns slowly intermittently to compensate for vacuum loss) for as long as that vacuum level holds. The rate at which the maximum set vacuum level is reached is directly proportional to the flow rate (Fig. 5.9.2).

### Vacuum-Based

These systems generate an adjustable level of vacuum in a chamber in the machine; usually, a Venturi pump is used. It is the pressure difference between this chamber and the tip that generates flow. Once the tip is occluded, fluid continues to be removed from the tubing until the pressure within it equals that in the vacuum chamber. It is possible, however, to introduce a damping effect into the system so that the equilibration

**Fig. 5.9.2** Vacuum rise-time as a function of aspiration rate. Graph showing the effect of increasing aspiration rate (pump speed) on the time to reach certain vacuum levels.

of pressures does not take place instantaneously. In a standard vacuum system, because the flow rate is generated by the pressure gradient, increasing the vacuum results in increased flow, whereas reducing vacuum lowers the flow. These two parameters cannot normally be modulated independently, although with at least one advanced machine, this is now possible.

## Anterior Chamber Hydrodynamics

It is important to understand the correct meaning of various terms used to describe the fluid dynamics of phaco. “Vacuum (Limit)” is taken to mean the preset maximum vacuum level indicated on the console. In neither peristaltic nor vacuum-based systems is this vacuum present in the AC, although some degree of vacuum must be present along the aspiration line (including in the phaco handpiece) to generate outflow. Normally, “flow” is used to mean aspiration flow rate, which is evacuation flow out of the eye. Fluid also flows out of the eye at a variable rate through the incisions, often called the *incision leakage flow*. To avoid confusion, if flow into the eye is being described, it is necessary to use the term “inflow.” In traditional phaco systems, the rate of fluid inflow is determined by the height difference between the drip chamber of the fluid reservoir (usually a hung bottle) and the eye. Inflow has been passive in traditional phaco machines; it is reduced in varying amounts by the resistance of the tubing and by any compression of the inflow sleeve around the phaco tip. The recently introduced “Centurion” phaco machine (Alcon) has an active inflow system allowing much more precise control of the AC dynamics and intraocular pressure. The system monitors the pressure in the inflow line, the vacuum pressure being generated in the outflow line and the aspiration flow rate, in real time, and adjusts the pressure being applied to the bag containing the inflow fluid in order to generate sufficient inflow to maintain (within limits) the intraocular pressure (IOP) chosen by the surgeon.

In any system (gravity-fed or with active fluidics) it is essential that the inflow potential (the maximum possible under free-flow conditions) at least equals, and if possible exceeds, the maximum transient outflow (combined incisional flow and machine-generated flow); otherwise AC collapse occurs (see “Postocclusion Surge” later). In a gravity-fed system (the traditional system), as the fluid bottle or bag is generally fixed during a given step in the procedure, the height of the bottle is set so that it will generate sufficient inflow during postocclusion surge to prevent AC collapse. For most surgeons, this is set at 80–95 cm above eye level, although some surgeons set the bottle even higher. When the phaco (or I/A) handpiece is in the eye with irrigation active (foot pedal position 1) then the eye is pressured to 80–95 cm H<sub>2</sub>O, which equates to 59–70 mm Hg. In an ex-vivo model it has been shown that during unoccluded aspiration (foot-pedal position 2) the IOP drops significantly because of resistance to inflow in a gravity-fed system. With an aspiration flow rate of 30 cc/min for example, with a fixed bottle height of 95 cm, the IOP drops from 70 mm Hg to 50 mm Hg<sup>6,7</sup> (Fig. 5.9.3). The effect of this is that during normal surgery with a

**Fig. 5.9.3** Actual intraocular pressure (IOP) with different aspiration flow rates. Graph showing how IOP drops with increasing aspiration in a gravity-fed system (two different manufacturers' machines). Monitored forced infusion system can overcome this. (Taken with permission from Boukhny M, Sorensen GP, Gordon R. Novel phacoemulsification system using feedback-based IOP target control. Presented at ASCRS Annual Meeting, Boston, April 25–29, 2014.)

gravity-based phaco system with these typical settings, the IOP will fluctuate during cataract removal between 70 and 50 mm Hg, depending on the foot-pedal position and the degree of tip occlusion. Only very briefly during postocclusion surge will it drop significantly lower than 50 mm Hg. The same ex-vivo study showed that the monitored forced infusion system produced no significant IOP changes with aspiration flow rates up to 60 cc/min.

In traditional longitudinal phaco, an active phaco tip (power-applied) produces forces that push material away from it. This is countered by the vacuum that holds the material to the tip. The torsional mode of the Infiniti (Alcon) generates a sweeping horizontal movement without repulsion, and lower vacuums can be used. When a surgeon uses a technique that involves sculpting (e.g., “divide and conquer”<sup>8</sup> or “stop and chop”<sup>9</sup>), a relatively low flow ( $\leq 25$  mL/min) with no tip occlusion is required (Video 5.9.1). The low flow allows sculpting near or even onto the capsule, without the risk of drawing the capsule into the port, and a tip slope of 30° or 45° allows the surgeon both to see the tip and to minimize occlusion potential. For subsequent nucleus fragment consumption (or initially in chop techniques), a high flow (20–40 mL/min) is required to pull the nucleus toward the tip, along with high vacuum (200–600 mm Hg) to hold it in contact for emulsification (Video 5.9.2). Occlusion in these circumstances is enhanced by rotation of the tip so that the opening is aligned with the edge of nucleus being grasped.

Many phaco systems now offer the surgeon the opportunity to adjust the fluidics performance, particularly vacuum rise-time, once occlusion has been achieved. One use is to have relatively low aspiration flow rates during the acquisition of nucleus fragments but set the machine to significantly increase the flow rate (and hence speed of achieving the preset vacuum) once the tip is occluded. Another example would be the reduction in flow rate on occlusion that some surgeons use when dealing with very soft cataracts or epinucleus.

## Fluidics of Microincisional Phaco

Since 2001, many surgeons have adopted the concept of microincisional phaco. This was first performed in a biaxial mode<sup>10</sup>; the infusion was dissociated from what became a “bare” aspiration tip by use of a separate cannula inserted through a separate incision. Each incision is only 1–1.5 mm wide, and there are a number of IOLs that can be inserted through sub-2-mm incisions. The reduced maximum incision size results in smaller changes to corneal curvature induced by the surgery. In coaxial phaco, the infusion ports in the infusion sleeve around the phaco tip are positioned close to the aspiration port and, therefore, can create turbulent flow that can disrupt the attractive force generated by aspiration. In theory, with biaxial phaco these forces are now separated and should result in better followability.

Critics of biaxial surgery point to the degraded fluidics that may be produced by a nonconforming bare solid cannula passing through a corneal incision; either incisional leakage must be significant, or the incision is so tight as to risk significant tearing of corneal stroma and Descemet's

membrane. New sleeves for coaxial microincision phaco have now been developed that allow coaxial phaco to be performed through 1.8-mm incisions.

Whether using biaxial or coaxial microincision techniques, it is important that surgeons understand the importance of fluidics and ensure that the inflow potential through the reduced sleeve, or the separate infusion instrument is greater than the maximum outflow during postocclusion surge with their particular combination of machine, needle, and vacuum settings.

## POSTOCCLUSION SURGE

With any pump design, in the occluded state, vacuum is generated in the lumen of the tubing. When the occlusion breaks, fluid rushes into the tubing to equilibrate the pressure difference between the AC and the lumen—“postocclusion surge” (Fig. 5.9.4). During the period of occlusion, the walls of the tubing tend to collapse in proportion to the increase in vacuum, and dissolved gas is pulled out of solution. On release of the occlusion the tubing re-expands and often rebounds, and the gas bubbles contract resulting in postocclusion surge. The difference between the outflow surge and the compensating inflow from the irrigation bottle determines the stability of the AC. Tubing with increased stiffness is said to have reduced compliance. Cassettes in the irrigation/aspiration line also have compliance, and a tendency exists for modern versions to have as much as possible of the fluid pathway in the cassette made of rigid material.

Phaco systems use a variety of other strategies to reduce the problems associated with postocclusion surge. The internal diameter of both the phaco needle (and any restrictions, such as seen in the flared needle) and outflow tubing modulate the outflow surge. Less compliant outflow tubing and cassettes reduce the rebound effect. Fig. 5.9.5 shows the impact of reducing tubing and cassette compliance in three generations of phaco equipment from a single manufacturer over a 10-year period. The effective inflow diameter (the gap between the outer wall of the tip and the inner wall of the sleeve in coaxial phaco, or the internal diameter and outflow port diameters of the irrigation instrument in biaxial phaco), along with the bottle height/irrigation pressure, determines the amount of inflow and how well it compensates for outflow surge. Manufacturers have different approaches to reducing the problems of postocclusion surge. These include reducing the vacuum after a given (surgeon-selected) time of full occlusion on the assumption that the occlusion is about to break. Others reduce the aspiration flow rate immediately after a sudden drop in vacuum is detected. When the vacuum at the tip suddenly decreases on occlusion break, a significant time lag occurs before the pressure-change information is propagated along the tubing to the phaco console. At least one manufacturer is exploring the possibility of having a pressure sensor in the handpiece to eliminate this time lag and thus speed up any programmed response to postocclusion surge.

However good the machine, surgeons need to understand the impact that choice of needle size/shape along with sleeve diameter and bottle height may have on AC stability.

5.9.2

**Fig. 5.9.4** Intraocular pressure (IOP) during postocclusion surge. IOP initially maintained by bottle height. Slight rise when tip occluded. When occlusion breaks, large pressure difference between tubing and anterior chamber (AC) results in rapid outflow of fluid causing IOP to drop rapidly until infusion restores "normal" IOP.

**Fig. 5.9.5** Reduction of postocclusion surge resulting from reduced outflow compliance with time. Postocclusion surge volumes at different vacuum limits for original Infiniti phaco machine (2003), Infiniti with "Intrepid" reduced compliance cassette and tubing (2006) and Centurion phaco machine (2013) with new cassette and tubing (Adapted with permission from data provided by Alcon.)

# Refractive Aspects of Cataract Surgery

Emanuel S. Rosen

# 5.10

**Definition:** Modern cataract surgery not only promises prevention of induced refractive errors by the surgical process but also the opportunity to enhance the eye's refractive status.

## Key Features

- Importance of the corneal shape before operation.
- Value of corneal topography.
- Prevention of induced corneal astigmatism.
- Treatment of astigmatism.
- Intraoperation.
- By incisions.
- By implant choice.
- Postoperation.
- By corneal laser surgery.
- By toric lens implantation.
- By piggyback lens implantation.

## INTRODUCTION

When Sir Harold Ridley implanted a human eye with a replacement lens (intraocular lens [IOL]) in 1949, he initiated a change in the role of cataract surgery.<sup>1</sup> As IOL implantation technology matured over the following years, cataract surgery became more than just removing a clouding crystalline lens; it allowed for the replacement IOL to be adjusted to correct intrinsic refractive error, or ametropia. In other words, there are two strategies for surgical intervention: first removing the impediment of a cataractous lens and then simultaneously incorporating an IOL of measured dioptric power to neutralize existing ametropia.

Of course, there are many other aspects to the refractive aspects of cataract surgery. Accurate biometry is vital (refer to that aspect of cataract management in the discussions in this section). Cataract surgery in eyes that have previously undergone corneal refractive surgery require special formulas to calculate the correct IOL power after keratometric values have been changed by that surgery. Management of astigmatism is a fundamental refractive need in cataract surgery and will be considered here. With the advent of clinical aberrometers and their application in refractive surgery, cataract replacement is now taking advantage of the deeper understanding of the relationship, in a refractive sense, between the cornea and the lens. Near, intermediate, and distance vision needs have to be satisfied by lens replacement, a task fulfilled by emergent multifocal IOL technology, pseudo-accommodative IOLs, and the future fulfillment of truly accommodating IOLs. The bases for refractive correction, as an aspect of cataract surgery, are accurate biometry on the one hand and corneal topography on the other.

The focus of cataract surgery is to correct the immediate aphakia. Current techniques and implants offer the opportunity to individualize patients' postoperative spherical and astigmatic errors and thus achieve overall patient satisfaction with regard to refraction.

Intraoperative techniques are the first to be applied (1) to ensure that astigmatism is not induced and (2) to neutralize it intraoperatively, if possible. Residual astigmatism after cataract surgery can be corrected by using four different techniques. These are (1) classic limbal relaxing incisions, which are easy to perform but have limited precision; (2) corneal laser refractive surgery (photorefractive keratotomy [PRK]); or (3) laser-assisted in situ keratomileusis (LASIK), additionally allowing for correction of spherical components; and (4) more recently, the use of a piggyback toric intraocular lens in the ciliary sulcus.<sup>2</sup>

## VALUE OF CORNEAL TOPOGRAPHY

Fig. 5.10.1 illustrates the importance of preoperative corneal topography in ensuring that the eye to be operated upon is fully understood: "Understand before you treat."

Corneal topography contributes significantly to our understanding of the requirements of cataract refractive surgery. It enables adjustments for astigmatism, when required, either intraoperatively or after the operation, while also detecting serious corneal issues before the operation to avoid unexplained poor postoperative visual acuity.

## INTRAOPERATIVE MANAGEMENT OF PREOPERATIVE CORNEAL ASTIGMATISM TO PREVENT INDUCTION OF CORNEAL ASTIGMATISM

### Corneal Incisions

In a randomized clinical trial and noncomparative interventional case series, Tejedor and Murube<sup>3</sup> investigated the best location for clear corneal incision (CCI) in phacoemulsification ("phaco"), depending on pre-existing corneal astigmatism.

In summary, for cataract CCIs:

- A superior incision is recommended for at least 1.5 D of astigmatism with a steep meridian at 90°.
- A temporal incision is recommended for astigmatism less than 0.75 D and steep meridian at 180°.
- A nasal incision is recommended for at least 0.75 D of astigmatism with a steep meridian at 180°.

Beltrame et al.<sup>4</sup> compared astigmatic and topographic changes induced by different oblique cataract incisions in 168 eyes having phaco, which were randomly assigned to one of three groups: (1) 3.5 mm CCI, 60 eyes (Figs. 5.10.1–5.10.7 for similar examples); (2) 5.5 mm sutured CCI, 54 eyes; and

**Fig. 5.10.1** Pellucid marginal corneal degeneration. An example where preoperative corneal topography would have revealed the defect that resulted in "unexplained" poor visual results after surgery.

**Fig. 5.10.2** Opposite clear corneal incision to correct preoperative astigmatism. Diagram to illustrate symmetry of incisions designed to correct each half of the steep meridian "bow tie."

**Fig. 5.10.4** Small clear corneal incision—no central effect. OZ, optical zone.

**Fig. 5.10.3** Clear corneal incision (2.5 mm).

**Fig. 5.10.5** Large clear corneal incision—more effect. OZ, optical zone.

(3) 5.5 mm scleral tunnel, 54 eyes. Incisions lay on the 120° semi-meridian. Corneal topography was performed preoperatively and 1 week, 1 month, and 3 months postoperatively. Simulated keratometric readings were used to calculate astigmatism amplitude and surgically induced astigmatism (SIA). Postoperative topographic changes were determined by subtracting the preoperative numeric map readings from the postoperative numeric map readings. At 3 months postoperatively, the mean SIA in the right and left eyes, respectively, was  $0.68 \pm 1.14$  D (SD) and  $0.66 \pm 0.52$  D in the 3.5 mm CCI group,  $1.74 \pm 1.4$  D and  $1.64 \pm 1.27$  D in the 5.5 mm CCI group, and  $0.46 \pm 0.56$  D and  $0.10 \pm 1.08$  D in the scleral tunnel group. Right and left eyes showed similar SIA amplitude but different SIA meridian orientation. SIA was significantly higher in the 5.5 mm CCI group than in the other two groups 1 and 3 months postoperatively ( $P < 0.01$ ). All groups showed significant wound-related flattening and non-orthogonal steepening at two opposite radial sectors. Topographic changes were significantly higher in the 5.5 mm CCI group and significantly lower in the scleral tunnel group.

Right and left eyes showed similar SIA amplitudes but different SIA meridian orientations and topographic modifications, probably because of the different supero-temporal and supero-nasal corneal anatomic structures. The 5.5 mm CCI induced significantly higher postoperative astigmatism, SIA, and topographic changes.

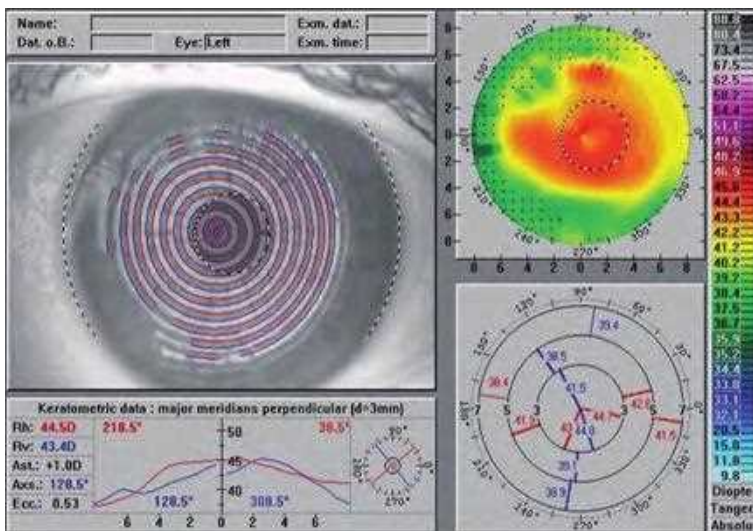

**Fig. 5.10.6** Topography map of 3-mm clear corneal incision. Peripheral flattening of cornea but no central effect.

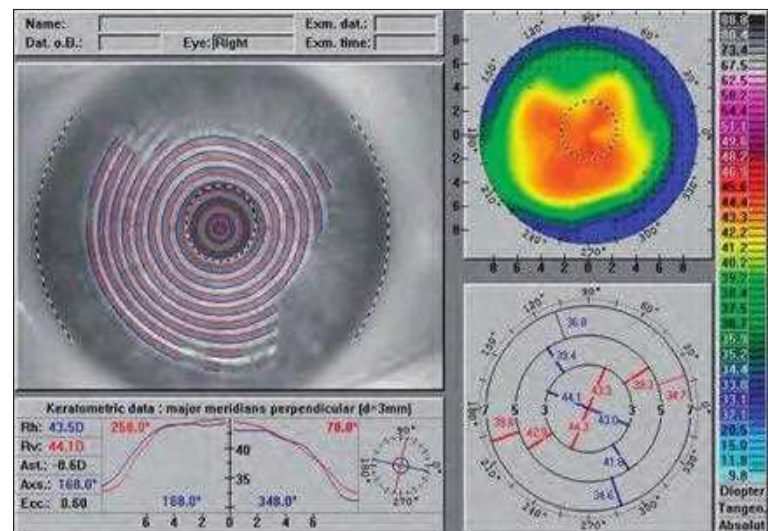

**Fig. 5.10.7** Topography map of 2.5-mm clear corneal incision. No peripheral flattening of the cornea or central effect.

**Fig. 5.10.9** Topography map of 3.7-mm clear corneal incision. (See the videokeratograph in Fig. 5.10.8.) The map illustrates the central effect of a larger peripheral clear corneal incision, with resulting nonorthogonal astigmatic hemi-meridia.

**Fig. 5.10.8** Videokeratograph of a 3.7-mm clear corneal incision. Note the localized flattening of the cornea close to incision, also affecting the optical zone.

**Fig. 5.10.10** Postoperative topography map following opposite clear corneal incision for 5 D astigmatism. Note the four hemi-meridia but no manifest or topographic astigmatism.

## TO TREAT PREOPERATIVE CORNEAL ASTIGMATISM

### Astigmatic Incisions

The cornea does not have axes but has only meridians, and all references to corneal incisions for the relief of astigmatic error in the cornea should be made to the “steep meridian.”

### Limbal Relaxing Incisions

Kaufmann et al.<sup>5</sup> compared limbal relaxing incisions (LRIs) with placement of the corneal cataract incision on the steepest keratometric meridian for the reduction of pre-existing corneal astigmatism at the time of cataract surgery. In a prospective single-center study, patients having 1.5 D or more of keratometric astigmatism were randomly assigned to two surgical techniques: on-steep meridian incisions (SMIs) consisting of a single CCI centered on the steepest corneal meridian; or LRIs consisting of two arcuate incisions straddling the steepest corneal meridian and a temporal CCI. After 6 months, the flattening effect was 0.35 D (range 0–0.96 D) and 1.10 D (range 0.25–1.79 D), respectively ( $P = 0.004$ ), thus confirming that the amount of astigmatism reduction achieved at the intended meridian was significantly more favorable with use of the LRI technique and remained consistent throughout the follow-up period.

### Opposite Clear Corneal Incisions

Lever and Dahan<sup>6</sup> were the first surgeons to demonstrate that in cataract surgery, the CCI has a small flattening effect on corneal curvature, which can be used to reduce pre-existing astigmatism (PEA). Adding an identical, penetrating CCI opposite the first one enhances the flattening effect. The extent of flattening affecting the optical zone of the cornea is dependent on the width of the clear corneal tunnel incision and the way it is constructed. Although a general algorithm can be devised, in general, it is incumbent upon each surgeon to devise his or her own algorithm, as the location of the incision, the knife used, and the length of the tunnel are difficult to standardize. Suffice it to say, the wider the incision and the more centrally it is placed, the greater will be its effect. The local flattening of the incision only has a central effect if it is wide enough. Figs. 5.10.2–5.10.15 illustrate all the incisions, their effects, and the healing process as depicted by corneal topography. It is recommended that surgeons wishing to utilize the technique should study the effects of their own CCIs through the medium of corneal topography and thereby derive a personal nomogram.

Paired opposite CCIs (OCCIs) are placed on the steepest meridian to achieve a reduction in the dioptric power of the central cornea. One CCI is used to perform cataract surgery, and the opposite CCI is made to ensure symmetry of the flattening effect and, therefore, to modulate PEA. Lever and Dahan<sup>6</sup> used 2.8- to 3.5-mm OCCIs in 33 eyes having PEA greater

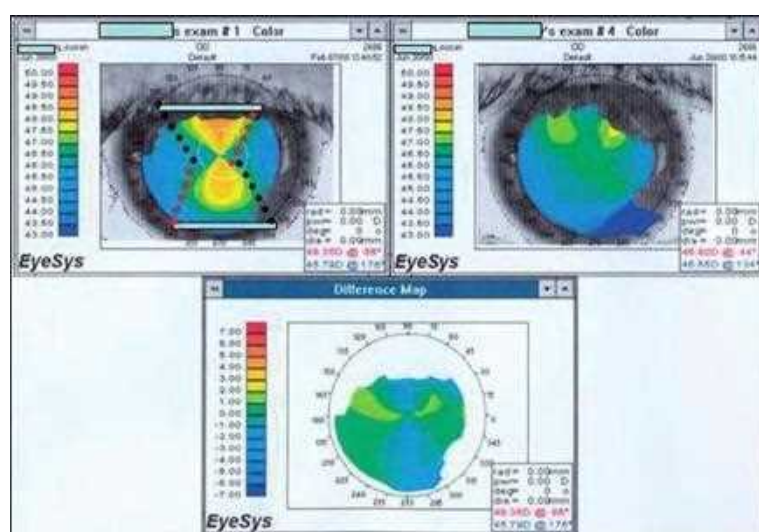

than 2.00 D and undergoing cataract surgery. The mean astigmatism correction achieved with this technique was 2.06 D. This technique is simple and effective and yields stable results that rival those of arcuate keratotomy. The OCCI technique has a potential application for the correction of astigmatism in general refractive surgery.

Qam-mar and Mullaney<sup>7</sup> evaluated the effect of OCCIs in correcting astigmatism on the steep corneal meridian axis in 14 patients with cataracts. They achieved a mean correction of astigmatism of  $1.23 \pm 0.49$  D (range 0.30–2.20 D). The mean surgically corrected astigmatism by vector analysis was  $2.10 \pm 0.79$  D (range 0.80–3.36 D). As other studies have shown,<sup>6–9</sup> paired OCCIs on the steep corneal meridian correct astigmatism in eyes undergoing cataract surgery with the use of routine surgical instruments.

The features of OCCIs may be summarized as follows:

- OCCIs cause negligible effect on spherical equivalence and, therefore, do not influence biometric calculations.
- Paired incisions are used for symmetric effect.
- Asymmetric OCCIs are used for asymmetric (“bow tie”) astigmatism.
- OCCIs are to be placed on a steep corneal meridian.

**Fig. 5.10.11** Preoperative, postoperative, and difference topography maps to illustrate opposite clear corneal incision (OCCI) effect. OCCI OD  $-15.5/+3.0 \times 90$  Plano post-op (4.5 mm OCCI); effect of each OCCI illustrated by dotted lines.

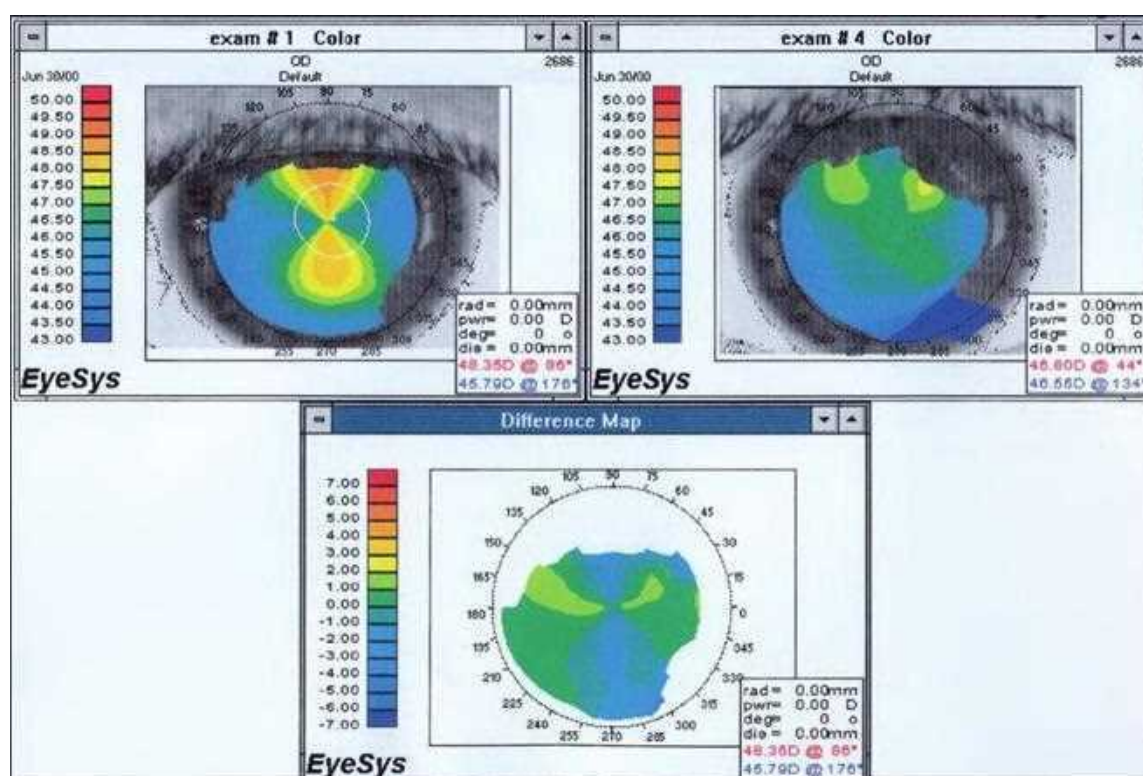

- The bulk of the cornea is preserved in case of need for correction of minor astigmatism with arcuate keratotomies.
- OCCIs also may be referred to as opposite penetrating astigmatic keratotomies (OPAKs).

## TORIC INTRAOCULAR LENS IMPLANTATION

Toric intraocular lenses can be used as an alternative or adjunct to corneal astigmatic incisions for correcting PEA in patients with cataracts. They are a particularly attractive option in those cases where LRIs or OCCIs are not powerful or predictable enough. Phaco extraction of a cataract through a small (astigmatically neutral) incision with toric intraocular lens implants (TIOLs) is an attractive alternative for patients with cataract and significant corneal astigmatism ( $> 1.5$  D). The elimination or reduction of preoperative astigmatism provides many patients with the prospect of clear distance vision without the aid of glasses.<sup>9–11</sup>

TIOLs for the correction of corneal astigmatism in cataractous and pseudophakic eyes. Accurate rotational stability and axial alignment are critical to the success of TIOL surgery. Factors that may influence the rotational stability of the TIOL include IOL design (plate haptic), overall haptic diameter, IOL material, and the eye's axial length. TIOL alignment meridian, size, and integrity of the capsulorrhexis, capsular bag dimensions, and postoperative healing/shrinkage. Despite accurate preoperative biometry and intraoperative alignment, patients may lose the benefits of astigmatism correction if the TIOL rotates after the operation.<sup>12–14</sup> Cataract surgery with TIOL allows the correction of high degrees of regular corneal astigmatism. Toric lens cataract surgery also is valuable as a secondary procedure, for example, after keratoplasty, with resultant higher degrees of regular residual astigmatism.<sup>15</sup>

Spontaneous rotation of a TIOL can occur and will require correction by surgical intervention to restore the IOL to its correct neutralizing alignment in astigmatism. An example of this is the case of a 23-year-old female with myopic astigmatism who underwent TIOL implantation. Preoperative uncorrected visual acuity (UCVA) was 20/800 and 20/1200, respectively, with  $-7.75 -4.25 \times 0^\circ$  and  $-8.25 -5.25 \times 180^\circ$ . In the left eye, an UCVA of 20/30 was achieved. After 3 months of successful implantation of TIOL in the left eye, the patient presented with a sudden decrease in visual acuity in this eye. UCVA was 20/100 with a refraction of  $+2.50 -4.50 \times 165^\circ$ . The toric marks showed a  $30^\circ$  rotation from the original position and required repositioning of the TIOL, resulting in a final UCVA of 20/25, which remained stable at 6 months' follow-up. A TIOL can undergo considerable rotation, and inevitably this will compromise visual acuity. Its relocation, therefore, is required, and more often than not, this will prove to be an effective procedure to recover visual acuity.<sup>16</sup>

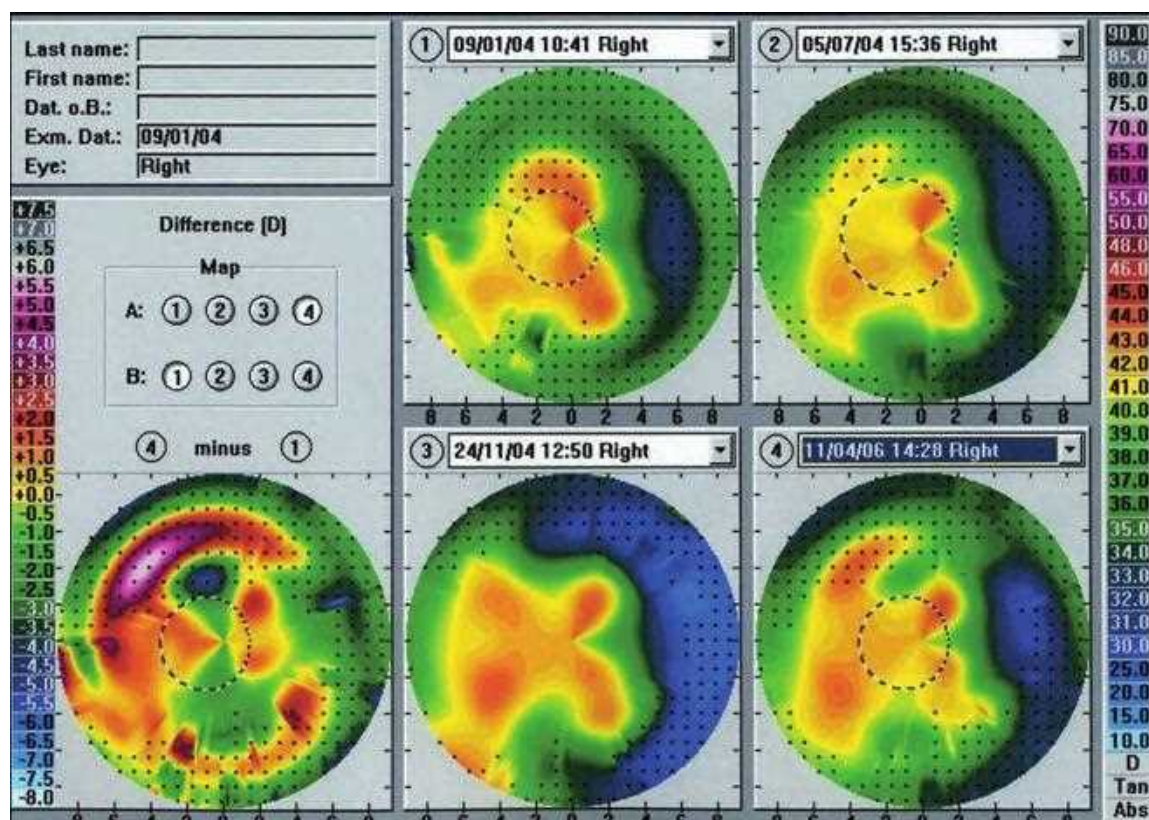

**Fig. 5.10.12** Preoperative, postoperative, and difference topography maps to illustrate opposite clear corneal incision effect. Opposite clear corneal incision (OCCI) OD  $-15.5/+3.0 \times 90$  Plano post-op (4.5 mm OCCI).

**Fig. 5.10.15** OD (right eye) pre-op +10.25/−4.5 × 175 ≡ 6/6–2 postoperative +0.25 ≡ 6/5 uncorrected visual acuity (UCVA) 6/5. Topography maps illustrating sequential healing responses of cornea to opposite clear corneal incision effect. Difference map illustrates flattening of original astigmatism. Manifest refraction virtually plano. Final map illustrates typical four hemi-meridia with spherical optical zone.

## LIGHT-ADJUSTABLE INTRAOCULAR LENS IMPLANT

Residual refractive errors after cataract and lens implant surgery are treated with corneal incisional surgery, excimer laser corneal surgery, or toric IOL primary or secondary implantation (piggyback lens implants), but a one-step planned refractive outcome remains desirable. The light-adjustable intraocular lens implant (LAL) offers the prospect of consulting room, postoperative, refractive adjustment of the provisional refractive outcome of the primary surgery, even though with secondary adjustment steps but without the requirement for further surgical intervention. The LAL incorporates a photosensitive silicone macromer in a medical-grade silicone polymer matrix. The photosensitive IOL component is 100 µm molded onto the posterior surface of the silicone optic of the IOL. This posterior layer has a higher concentration of ultraviolet (UV) light absorber compared with the anterior portion of the implant optic. Selective irradiation of the LAL uses a specific UV (365 nm) beam to irradiate the IOL and produces a controlled spherical and/or cylindrical power change; this is undertaken a few weeks postoperatively, when the eye's refraction has stabilized after the cataract surgery. In the interim period, the patient has to wear UV-filtering glasses to prevent unwanted UV radiation entering the eye before it is appropriate to apply the selective exposure, after which the refractive power of the implant is locked in. Postoperative studies with longer-term follow-up are impressive.<sup>26–28</sup>

# Small Incision and Femtosecond Laser-Assisted Cataract Surgery

Mark Packer

# 5.11

**Definition:** Small incision cataract surgery is the extraction of the lens through a corneal incision designed to be self-sealing.

## Key Features

- The refinement of incision placement and architecture, as well as the reduction of final incision size occasioned by the implantation of a foldable, injectable intraocular lens, permits the reduction of postoperative astigmatism and enhancement of refractive cataract surgery.
- Continuous curvilinear capsulorhexis facilitates sculpting techniques, such as divide and conquer, trending to today's preferred horizontal and vertical chopping methods.
- Hydrodissection to lyse cortical–capsular connections.
- Hydrodelineation to permit phaco within the protective layer of the epinucleus improves the safety and efficiency of phaco.
- Power modulations, such as millisecond level control of ultrasound power application, allow for reduction of the energy required for cataract extraction, protection of the cornea from thermal injury, and enhancement of the rapidity of postoperative visual rehabilitation.
- Femtosecond laser-assisted surgery represents a relatively new technology that some surgeons have adopted for cataract extraction.

## Associated Feature

- The separation of irrigation from aspiration made possible through biaxial microincision phaco represents an advance in control of the fluidic behavior of the intraocular environment, permitting greater versatility in every step of the cataract extraction procedure.

## INTRODUCTION

The principal technical features of phaco include the following:

- Watertight, self-sealing corneal incisions.
- Intact, round, centered capsulorhexis with a diameter smaller than that of the intended intraocular lens (IOL) optic.
- Efficient ultrasound power modulation and fluidics to protect the capsule, iris, and cornea.
- Fastidious cortical cleanup, resulting in a clean capsular bag.
- Atraumatic IOL insertion through an incision of 1.5–2.4 mm.

“Phaco” refers to the techniques and technology required for the fragmentation and extraction of the crystalline lens through a small corneal incision and the implantation of an intraocular lens (IOL), resulting in rapid visual rehabilitation and reduced need for optical correction.

Since the time of its introduction in the late 1960s, phaco has evolved into a highly effective method of cataract extraction. Incremental advances in surgical technique and the simultaneous redesign and modification of technology have permitted increased safety and efficiency. Among the advances that have shaped modern phaco are incision construction, continuous curvilinear capsulorhexis, cortical cleaving hydrodissection and hydrodelineation, and nucleofractis techniques.

The United States patent #3589363, filed July 25, 1967, lists Anton Banko and Charles D. Kelman as inventors of “an instrument for breaking apart and removal of unwanted material, especially suitable for surgical

operations such (as) cataract removal, including a handheld instrument having an operative tip vibrating at a frequency in the ultrasonic range with an amplitude controllable up to several thousandths of an inch.”<sup>1</sup>

Even until recently, the fundamental mechanisms by which the system known as “phaco” operates has remained controversial. Although some authors have described the surgical advantages of a unique type of cavitation energy, others have denied any role for cavitation energy in phaco.<sup>2</sup>

## INCISION CONSTRUCTION AND ARCHITECTURE

Since 1992, when Fine described the self-sealing temporal clear corneal incision (CCI), the availability of foldable IOLs has furthered the trend away from scleral tunnel incisions to clear corneal incisions.<sup>3</sup> Rosen demonstrated through topographic analysis that CCIs 3 mm or less in width do not induce significant astigmatism.<sup>4</sup> This finding led to increasing interest in T-cuts, arcuate cuts, and LRIs for managing pre-existing astigmatism at the time of cataract surgery. Surgeons recognized many other advantages of the temporal CCI, including better preservation of the conjunctiva, increased stability of refractive results because of decreased effects from lid blink and gravity, ease of approach, elimination of the bridge suture and iatrogenic ptosis, and improved drainage from the surgical field via the lateral canthal angle.

Surgeons originally adopted single-plane incisions utilizing a 3-mm diamond knife. After pressurizing the eye with viscoelastic through paracentesis, the surgeon placed the blade on the eye so that it completely applanated the eye, with the point of the blade positioned at the leading edge of the anterior vascular arcade. The knife was advanced in the plane of the cornea until the shoulders, 2 mm posterior to the point of the knife, touched the external edge of the incision. Then, the point of the blade was directed posteriorly to initiate the cut through Descemet's membrane in a maneuver known as the *dimple-down technique*. After the tip entered the anterior chamber, the initial plane of the incision was re-established to cut through Descemet's membrane in a straight-line configuration.

Williamson was the first to utilize a shallow 300–400  $\mu$ m grooved CCI.<sup>5</sup> Langerman later described the single-hinge incision, in which the initial groove measured 90% of the depth of the cornea anterior to the edge of the conjunctiva.<sup>6</sup> Surgeons employed adjunctive techniques to combine incisional keratorefractive surgery with CCIs. Osher described the construction of arcuate keratotomy incisions at the time of cataract surgery for correction of pre-existing corneal astigmatism. Kershner used the temporal incision by starting with a nearly full-thickness T-cut, through which he then made his corneal tunnel incision.<sup>7</sup> Finally, the recommendation of LRIs by Gills and Nichamin advanced what ultimately became most popular means of reducing pre-existing astigmatism.<sup>8,9</sup>

Following phaco, lens implantation, and removal of residual viscoelastic, stromal hydration may be performed to seal the incisions by gently irrigating balanced salt solution into the stroma at both edges of the incision with a 26- or 27-gauge cannula. An intraoperative Seidel test may be used to ensure sealing. Studies of sequential optical coherence tomography of postoperative CCIs have demonstrated that the edema from stromal hydration lasts up to 1 week.<sup>10</sup>

CCIs, by nature of their architecture and location, are associated with unique complications. Chemotic ballooning of the conjunctiva may occur as a result of irrigating fluid streaming into an inadvertent conjunctival incision. In this case, the conjunctiva may be snipped to permit decompression. Incisions that are too short can result in an increased tendency for iris prolapse and poor sealability. A single suture may be required to

**Fig. 5.11.1** Backward traction on the capsular flap forms the basis of a predictable technique for rescuing the capsulorrhexis from a radial tearout. As shown here in the case of an opaque cataract with trypan blue capsule stain, the tear has extended too far to the periphery (A). Therefore, the flap is unfolded and laid back in the plane of the capsulorrhexis from where it was torn (B). The flap is then pulled with reverse tangential force until the capsule tears back toward the center (C). Construction of the capsulorrhexis may then continue (D).

secure the wound. In contrast, a long incision may result in striae in the cornea that compromise the surgeon's view during phaco. Coarse manipulation of the phaco tip may result in epithelial abrasions or tears in Descemet's membrane, compromising self-sealability. Of great concern is the risk of incisional burns.<sup>11</sup> When incisional burns develop in CCIs, rapid contraction of tissue and loss of self-sealability occur. Suture closure of the wound may induce excessive astigmatism.

The literature supports the view that suboptimal construction of CCIs may lead to poor coaptation, inadequate sealing, and ingress of bacteria, thereby increasing the risk of acute postoperative bacterial endophthalmitis.<sup>12</sup> However, four large published series have found no greater likelihood of infection with corneal versus other types of incisions.<sup>13–16</sup> Regardless of the type of incision, the principle to be followed is that appropriate incision construction and watertight closure are obligatory. Besides poor wound closure, other significant factors that have been associated with higher risk of postoperative infection include posterior capsule rupture, vitreous loss, older age, prolonged surgery, immunodeficiency, active blepharitis, lacrimal duct obstruction, inferior incision location, and male gender.<sup>17</sup>

## CONTINUOUS CURVILINEAR CAPSULORRHEXIS

Implantation of the IOL in an intact capsular bag facilitates the permanent rehabilitative benefit of cataract surgery. For many years, surgeons considered a “can opener” capsulectomy to be satisfactory for both planned extracapsular cataract extraction and phaco. However, in 1991, Wasserman et al. performed a postmortem study that showed that the extension of one or more V-shaped tears toward the equator of the capsule produced instability of the IOL and resulted in malpositioning of the IOL.<sup>18</sup> Gimbel and Neuhann popularized continuous curvilinear capsulorrhexis (CCC) in the later 1980s.<sup>19–21</sup>

The basic principles of manual CCC include the following:

- The continuous capsular tear should be performed in a stable anterior chamber under pressurization by an ophthalmic viscosurgical device (OVD).
- The tear should be initiated at the center of the capsule so that the origin is included within the circle of the tear.
- The continuous tear may proceed either clockwise or counterclockwise in a controlled and deliberate fashion, the surgeon regripping with the forceps or repositioning the point of the cystotome/bent needle on the inverted flap to control the vector of the tear.

A tear that begins moving peripherally or radially is a signal that an existing condition requires immediate attention. Further progress of the

tear should be stopped and the depth of the anterior chamber assessed. Frequently, the cause of the peripheral course of the tear is shallowing of the anterior chamber. Adding more OVD to deepen the anterior chamber opposes the posterior pressure, making the lens capsule taut, widening the pupil, and permitting inspection of the capsule (Video 5.11.1).

One important technique for redirection of the capsulorrhexis has been described by Little.<sup>22</sup> In this technique, to rescue the capsulorrhexis from a peripheral tearout, the force applied to the capsular flap is reversed but maintained in the plane of the anterior capsule. It is necessary to first unfold the capsular flap so that it lies flat against the lens cortex, as it did prior to being torn. Force can then be applied with the capsule forceps by holding the capsular flap as close to the root of the tear as possible and pulling backward in a retrograde direction along the circumferential path of the completed portion of the capsulorrhexis. Traction should be applied in the horizontal plane of the capsule and not upward. The initial pull should be circumferentially backward and then, while holding the flap under tension, directed more centrally to initiate the tear. The forward progress of the capsulorrhexis will uniformly and predictably redirect toward the center of the capsule (Fig. 5.11.1). If the capsule will not tear easily and the entire lens is being pulled centrally, this rescue maneuver should be abandoned to avoid a wrap-around capsular tear or zonular dialysis. Other rescue techniques, such as completing the capsulorrhexis from the opposite direction or making a relieving cut in the flap edge and continuing in the same direction, represent reasonable alternatives.

The use of trypan blue to stain the anterior capsule in the absence of a good red reflex constitutes an important adjunctive technique for capsulorrhexis construction. The dye may be injected into the chamber through paracentesis under air. The air and residual dye are then exchanged for viscoelastic. Despite the absence of a red reflex, the capsule is easy to see.

The technique of CCC has provided important advantages both for cataract surgery and IOL implantation. Because endolenticular or in situ phaco must be performed in the presence of an intact continuous capsulectomy opening, capsulorrhexis has served as a stimulus for modification of phaco techniques. The edge of a well-constructed rhexis completely overlaps the edge of the IOL, ensuring positional stability and enhancing refractive predictability.

## HYDRODISSECTION AND HYDRODELINEATION

Hydrodissection has traditionally meant injection of fluid into the cortical layer of the lens to separate the nucleus from the cortex and the capsule. Following the adoption of capsulorrhexis, hydrodissection became a critical step to mobilize, disassemble, and remove the nucleus. Fine first described

cortical cleaving hydrodissection, which is designed to cleave the cortex from the capsule and leave the cortex attached to the epinucleus.<sup>23</sup> Cortical cleaving hydrodissection often eliminates the need for cortical cleanup as a separate step in cataract surgery.

In this technique, the anterior capsular flap is initially elevated with a 26-gauge blunt cannula. Firm and gentle continuous irrigation results in a fluid wave that cleaves the cortex from the posterior capsule. The lens bulges forward because fluid is trapped by equatorial cortical–capsular connections. Depressing the central portion of the lens with the side of the cannula forces fluid around the equator and lyses the cortical–capsular connections. Adequate hydrodissection is demonstrated by rotation of the nuclear–cortical complex. The demonstration of free rotation of the lens within the capsule represents a critical step in phaco.

Hydrodelineation describes separation of the epinuclear shell from the endonucleus by irrigation. The epinucleus acts as a protective cushion within which phaco forces can be confined. Further, the epinucleus keeps the bag on stretch throughout the procedure, making capsule rupture less likely.

To perform hydrodelineation, a 26-gauge cannula is placed in the nucleus, off center to either side, and directed at an angle downward and forward toward the central plane of the nucleus. When the nucleus starts to move, the endonucleus has been reached. At this point, the cannula is directed tangentially to the endonucleus, and a to-and-fro movement of the cannula is used to create a tunnel within the epinucleus. The cannula is backed out of the tunnel approximately halfway, and gentle but steady pressure on the syringe allows fluid to enter the distal tunnel without resistance. A circumferential golden or dark ring will appear, outlining the endonucleus.

Occasionally, an arc, rather than a complete ring, will result, surrounding approximately one quadrant of the endonucleus. In this instance, the procedure can be repeated in multiple quadrants until a golden or dark ring confirms complete circumferential separation of the endonucleus from the epinucleus.

## NUCLEOFRACTIS TECHNIQUES

The recognition that the lens nucleus could be divided and removed from within the protective layer of the epinucleus while preserving the capsulorrhexis influenced the development of a plethora of phaco techniques.

### Divide and Conquer

In the divide-and-conquer technique originally described by Gimbel,<sup>24</sup> a deep crater is sculpted into the center of the nucleus, including the posterior plate. However, phaco fracture, described by Shepherd, is often referred to as a “divide and conquer” technique.<sup>25</sup> In this technique, the surgeon sculpts a groove parallel to the incision one and a half to two times the diameter of the phaco tip, with the tip in a bevel-up position, using moderate power and low vacuum. Using the phaco handpiece and a second instrument, the surgeon then rotates the nucleus by 90° and sculpts a second groove perpendicular to the first. Sculpting continues until the red reflex is seen at the bottom of the grooves. A bimanual cracking technique is used to create a fracture through the nuclear rim in the plane of one of the grooves. The nucleus is then rotated by 90°, and additional fractures are made until four separate quadrants are isolated. A short burst of phaco power with increased vacuum then is used to embed the phaco tip into one quadrant, which is pulled into the center for emulsification. The second instrument can help elevate the apex of the quadrant to facilitate its mobilization.

### Phaco Chop

Nagahara first introduced the “phaco chop” technique by using the natural fault lines in the lens nucleus to create cracks without creating prior grooves (Presentation at the American Society of Cataract and Refractive Surgery Film Festival, 1993). The phaco tip is embedded in the center of the nucleus after the superficial cortex is aspirated. In horizontal chopping, a second instrument, the phaco chopper, is then passed to the equator of the nucleus, beneath the anterior capsule, and drawn to the phaco tip to fracture the nucleus. The two instruments are separated to widen the crack. In vertical chopping, a sharp-tipped instrument is inserted directly into the nucleus beside the embedded phaco needle, and the two instruments are again separated as in horizontal chopping. The nucleus is rotated, and this procedure is repeated until several small fragments are created, which are then emulsified.

## POWER MODULATIONS

Fine described the “choo-choo chop and flip” technique in 1998 and subsequently correlated the reduction of ultrasound energy made possible by power modulations with superior uncorrected visual acuity on the first post-operative day.<sup>26,27</sup> Effective phaco time (EPT), absolute phaco time (APT), and cumulative dissipated energy (CDE) have become standard metrics for the utilization of ultrasound energy. Although EPT, APT, and CDE cannot be compared across different machines made by different manufacturers, when using the same machine, they can be compared from one case to the next as a sign of surgical efficiency.

In Fine’s technique, a 30° straight phaco tip is used bevel down. After aspirating the epinucleus uncovered by capsulorrhexis, a horizontal chopper is placed in the golden ring by touching the top center of the nucleus with the tip and pushing the tip peripherally so that it slides beneath the capsulorrhexis. The chopper is used to stabilize the nucleus by lifting and pulling toward the incision slightly, after which the phaco tip “lollipops” the nucleus in either pulse mode at 2 pulses per second or at the 80-millisecond burst mode. Burst mode utilizes fixed power and duration with variable interval. In pulse mode, there is variable power with fixed duration and interval. These power modulations reduce total ultrasound energy and increase hold. Once the tip is buried in the center of the nucleus, vacuum is maintained in foot position 2. The nucleus is scored by bringing the chopper to the side of the phaco needle. It is chopped in half by pulling the chopper to the left and slightly down while moving the phaco needle, still in foot position 2, to the right and slightly up (Fig. 5.11.2). Then, the nuclear complex is rotated by 90°. The chop instrument is again brought into the golden ring, the hemi-nucleus is lollipopped, scored, and chopped with the resulting wedge now lollipopped on the phaco tip and evacuated. The nucleus is rotated so that wedges can be scored, chopped, and removed by high vacuum assisted by short bursts or pulses of phaco. The size of the wedges is varied according to the density of the nucleus.

After evacuation of all endonuclear material, the epinuclear rim is trimmed in each of the three quadrants, mobilizing the cortex. As each quadrant of the epinuclear rim is rotated to the distal position in the capsule and trimmed, the cortex in the adjacent capsular fornix flows over the floor of the epinucleus and into the phaco tip. The floor is pushed back to keep the bag on stretch until three of the four quadrants of the epinuclear rim and cortex have been evacuated. The epinuclear rim of the fourth quadrant is then used as a handle to flip the epinucleus. As the remaining portion of the epinuclear floor and rim is evacuated from the eye, the entire cortex is often evacuated with it.

If there is remaining cortex after removal of all the nucleus and epinucleus, there are three options. The phaco handpiece can be left high in the anterior chamber while the second handpiece strokes the cortex-filled capsular fornices. Frequently, this results in floating the cortical shell as a single piece and aspirating it through the phaco tip (in foot position 2) because cortical cleaving hydrodissection has cleaved most of the cortical–capsular adhesions.

Alternatively, if one wishes to complete cortical cleanup with the irrigation–aspiration handpiece prior to lens implantation, the residual cortex can almost always be mobilized as a separate and discrete shell and removed without turning the aspiration port down to face the posterior capsule.

The third option is to visco-dissect the residual cortex by injecting a dispersive viscoelastic through the posterior cortex onto the posterior capsule. The viscoelastic material spreads horizontally, elevating the posterior cortex and draping it over the anterior capsular flap. At the same time, the peripheral cortex is forced into the capsular fornix. The posterior capsule is then deepened with a cohesive OVD, and the IOL is implanted, leaving anterior residual cortex anterior to the IOL. Removal of residual OVD material accompanies mobilization and aspiration of the residual cortex.

Nonlinear delivery of ultrasonic or sonic frequencies, such as torsional and elliptical phaco, has further improved operating efficiency. Chopping techniques in combination with power modulations and nonlinear ultrasound power delivery minimize morbidity and enhance the rapidity of visual rehabilitation.

## BIAXIAL MICROINCISION CATARACT SURGERY

Advances in ultrasound engineering during the late 1990s led to the application of millisecond-level control and variable duty cycles in phaco, vastly reducing the risk of thermal injury from the phaco needle and permitting removal of the irrigation sleeve. Separation of irrigation from aspiration

**Fig. 5.11.2** The surgeon performs the initial chop of the nucleus by deeply embedding the phaco needle in the center of the nucleus using ultrasound power, and then maintaining a hold on the nucleus with high vacuum in foot pedal position 2 without ultrasound as the horizontal chopper is brought from the golden ring to the side of the phaco needle to score the nucleus. The surgeon then completes the chop by separating the instruments with a slight upward movement of the phaco tip and a slight downward movement of the chopper (A). Each quadrant of nuclear material is in turn impaled, chopped, mobilized, and consumed with high vacuum and low amounts of ultrasound power (B). Finally, the epinuclear shell is flipped with a helpful push from the chopper (C).

during phaco came to be known as *biaxial microincision cataract surgery* (B-MICS) (Video 5.11.2).

The advantages of B-MICS include better followability because of the separation of infusion and aspiration, access to 360° of the capsular bag with either infusion or aspiration by switching instruments from one hand to the other, the ability to use the flow of irrigation fluid as a tool to move material within the capsular bag or anterior chamber (particularly from an open-ended irrigating chopper or manipulator), prevention of iris billowing and prolapse in cases of intraoperative floppy iris syndrome, and significantly decreased risk of vitreous prolapse in the case of a posterior capsular tear, zonular dialysis, or subluxated cataract, thanks to maintenance of a pressurized stream of irrigation.

Perhaps the greatest advantage of the biaxial technique lies in its ability to remove the subincisional cortex without difficulty. As originally described by Brauweiler, by switching infusion and aspiration handpieces between two microincisions, 360° of the capsular fornices are easily reached, and cortical cleanup can be performed quickly and safely.<sup>28</sup>

Since dispersive OVDs do not easily extrude through these small incisions, the anterior chamber is more stable during capsulorhexis construction, and there is much less likelihood of an errant tear. This added margin of safety is particularly noticeable in cases of zonular compromise, such as pseudo-exfoliation and traumatic zonular dialysis (Fig. 5.11.3). The added chamber stability also can make a difference in control of the capsulorhexis in both high myopia and high hyperopia with an extremely deep or a very shallow anterior chamber, respectively (Video 5.11.3).

## B-MICS VERTICAL CHOP TECHNIQUE

After hydrodissection and hydrodelineation, the phaco needle is first embedded proximally with high vacuum and 40% power. In the other hand is a vertical chopper that will be used to split the nucleus. As vacuum builds to occlusion a rapid rise time enables the phaco needle to quickly grasp the endonucleus. At the point occlusion is reached, the aspiration flow rate drops to zero. The surgeon then moves into foot position 2 so that high vacuum is maintained and the power drops to zero. The blade of the irrigating vertical chopper is brought down just distal to the phaco tip. As a full-thickness cleavage plane develops, dividing the nucleus in two, the instruments are separated to insure a complete chop (Fig. 5.11.4).

The lens is then rotated with the irrigating chopper so that the first hemi-nucleus can be chopped. If there is a disparity in size, the larger half is moved distally. The phaco needle is now embedded to the right by using high vacuum and low levels of power. A quadrant size piece is chopped off and consumed (Fig. 5.11.5). The remaining quadrant of the first hemi-nucleus is then impaled with the phaco tip and aspirated. Total EPT to this point is zero, showing minimal usage of ultrasound.

**Fig. 5.11.3** The capsulorhexis is nearly complete in this eye with a history of trauma and 90° of zonular dialysis visible temporally. The wrinkling of the capsule is a clear sign of the lack of zonular tension. Nevertheless, because of the increased control allowed by the micro-incisions, which prevent extrusion of viscoelastic, the capsulorhexis will be centered, round, and smaller in diameter than the intraocular lens (IOL) as intended.

To address the second half of the nucleus, it is first rotated with the irrigating chopper so that it is in the distal capsule. The phaco needle is embedded in the smaller hemi-nucleus, and this is subdivided with the irrigating chopper, again using high vacuum and low levels of power (Fig. 5.11.6). As the final quadrant is grasped and pulled centrally for aspiration, the sharp blade of the irrigating chopper is turned sideways as a safety precaution (Fig. 5.11.7).

When addressing the epinucleus, the vacuum and aspiration flow are reduced. Once three quadrants of the epinuclear shell have been rotated and trimmed, the final quadrant is used to flip the epinuclear bowl into the phaco needle. After aspiration of the epinucleus, the capsule is almost entirely clean of cortex (Fig. 5.11.8).

B-MICS with a vertical chop technique allows for efficient lens extraction with rapid visual rehabilitation. This procedure demonstrates some of the tangible benefits of separating inflow from outflow, use of irrigation fluid as an instrument to mobilize material, and reduced effective phaco time (Video 5.11.4).

**Fig. 5.11.4** The phaco tip is embedded in the proximal nucleus bevel down; the nucleus is then held with high vacuum as the irrigating chopper slices vertically downward distal to the phaco tip. The chopper and the phaco tip are then separated as shown, to divide the nucleus.

**Fig. 5.11.7** The final segment of nucleus is grasped with high vacuum and brought centrally.

**Fig. 5.11.5** A quadrant-sized piece of nucleus is chopped and brought centrally, where it will be emulsified and aspirated.

**Fig. 5.11.8** At the conclusion of epinucleus aspiration, the capsule is almost entirely free of cortex.

**Fig. 5.11.6** A wedge of nucleus is chopped from the remaining hemi-nucleus.

## FEMTOSECOND LASER-ASSISTED CATARACT SURGERY

Femtosecond lasers have a unique ability to create discreet photodisruption of tissue with minimal collateral effects. This enables very precise cutting in ocular tissues, including the cornea, the lens capsule, and the crystalline lens.

Femtosecond lasers are indicated for the following surgical steps:

- Anterior capsulectomy.
- Lens fragmentation.
- Corneal arcuate incisions for treatment of astigmatism.
- Clear corneal incisions.

### Anterior Capsulectomy

Laser capsulectomy brings precision and reproducibility to the process of creating a capsular opening. Studies have shown that laser capsulectomies are significantly closer to the intended diameter than manual CCCs ([Table 5.11.1](#)).<sup>29,30</sup> However, concerns have arisen with regard to their resistance to tearing, which may be related to the surgeon's learning curve.

The size of the capsulectomy may influence the progression of posterior capsular opacification (PCO). Current practice requires that capsulectomy be in contact with the optic of the IOL around its circumference.

TABLE 5.11.1 Capsulectomy Data by Group

Differences are significant ( $P = 0.03$ ).

Group	Capsulectomy/Capsulorrhexis Diameter (mm)		
	Attempted	Measured	Attempted–Achieved
Laser ( $n = 49$ )			
Mean	5.23	5.08	0.16
SD	0.06	0.18	0.17
CCC ( $n = 24$ )			
Mean	5.36	4.95	0.42
SD	0.55	0.53	0.54

CCC, continuous curvilinear capsulorrhexis; SD, standard deviation.

TABLE 5.11.2 Percentage of Cases Achieving the Required Refractive Outcome

Deviation	6 Months After Surgery	
	Laser	Manual
0.00	13.5%	3.4%
$\leq 0.50$	81.1%	74.6%
$\leq 1.25$	100.0%	96.6%

From Uy H, Hill WE, Edwards K. Refractive results after laser anterior capsulotomy. *Invest Ophthalmol Vis Sci* 2011;52:5695.

However, significant variations in the extent of this contact or areas where there is no contact may cause the lens to decenter and tilt as the capsule contracts postoperatively.

Kranitz and Nagy reported improved overlap of the capsulectomy edge on the optic of the IOL and less horizontal decentration of the IOL in cases where laser capsulectomy had been used.<sup>31,32</sup> It has been proposed that the consistency of laser capsulectomy may increase the consistency of effective lens position (ELP) and hence the ability to hit the targeted postoperative refractive result. Early data presented by Uy and Hill confirm this effect.<sup>33,34</sup> In a study of 44 cases undergoing laser capsulectomy and 62 cases undergoing manual CCC, a significantly higher proportion produced the intended refractive outcome at 6 months by a factor of 4. Table 5.11.2 shows results supporting the hypothesis that laser capsulectomy has a positive effect on the consistency of ELP.

## Lens Fragmentation

Fragmentation of the lens prior to cataract surgery is intended to reduce or eliminate the need to use ultrasound energy during disassembly of the nucleus. In the ideal situation, the nucleus would simply be removed by aspiration. However, it might be anticipated that harder nuclei will require some ultrasound emulsification.

In the quest for optimal outcomes, different cutting patterns and algorithms (shot placement, energy, and pulse repetition frequency) may all influence the efficiency of the fragmentation. Nichamin has shown some of the patterns that were evaluated during an early phase of the development of lens fragmentation.<sup>35</sup> It was found that different patterns had different degrees of effectiveness, depending on the hardness of the cataract being treated. Overall, the pie pattern proved the most effective over the range of cataract grades from 1–5+.

Packer and Uy have presented data on the effectiveness of phaco-fragmentation by comparing the total ultrasound energy required for disassembly of the nucleus after laser lens fragmentation with that required during conventional ultrasound phaco surgery. Their results are shown in Tables 5.11.3 and 5.11.4.<sup>36</sup>

The reduction in the use of ultrasound energy may lead to other benefits, such as less corneal edema, faster visual recovery, and a reduction in the rate of endothelial cell loss. Packer and Uy reported that endothelial cell density changes from baseline are less following laser lens fragmentation compared with conventional ultrasound phaco. Table 5.11.5 summarizes these results.

TABLE 5.11.3 Analysis of Mean (SD) CDE as a Function of Nuclear Cataract Grade

Treatment Groups	For Grade 0 Mean (SD) N	For Grade 1 Mean (SD) N	For Grade 2 Mean (SD) N	For Grade 3 Mean (SD) N	For Grade 4 Mean (SD) N
Laser treatments	1.9 (3.2) 3	0.0 (0.0) 4	3.0 (4.0) 29	9.3 (9.4) 25	24.0 (18.8) 27
Control group	7.8 (–) 1	4.4 (2.4) 7	8.2 (6.1) 24	15.2 (13.0) 15	41.2 (24.7) 7
% Difference (control vs laser)	–75.6%	–100.0%	–63.4%	–38.8%	–41.7%

TABLE 5.11.4 Numbers of Subjects and Statistical Significance by Cataract Grade

Grade $\leq 1$		Grade 1		Grade 2		Grade 3		Grade 4	
Laser	Phaco	Laser	Phaco	Laser	Phaco	Laser	Phaco	Laser	Phaco
$N = 7$	$N = 8$	$N = 4$	$N = 7$	$N = 29$	$N = 24$	$N = 25$	$N = 15$	$N = 27$	$N = 7$
$P = 0.006$		$P = 0.006$		$P < 0.001$		$P = 0.069$		$P = 0.052$	

TABLE 5.11.5 Changes in Endothelial Cell Density Between Baseline and 3 Months After Surgery

	Grade 1		Grade 2		Grade 3		Grade 4	
	Laser	Phaco	Laser	Phaco	Laser	Phaco	Laser	Phaco
Mean % change	1.5	–7.0	0.1	–1.3	–0.1	–4.3	–2.4	–1.5

P value	$0.10 > P > 0.05$		NS		$0.10 > P > 0.05$		NS	

SD, standard deviation.

## Corneal Incisions

In an early study with cadaver eyes, Masket showed the ability of a single-plane laser incision to be self-sealing at significant intraocular pressures (IOPs) and indentations at certain wound tunnel lengths.<sup>37</sup> Palanker reported that three-plane laser incisions were self-sealing and watertight at physiological IOPs.<sup>38</sup> It is not clear whether this applies to the incision immediately after its creation or at the end of the surgical cases, following the use of the phaco handpiece and IOL insertion. Fig. 5.11.9 shows the planned corneal incision and the optical coherence tomogram of the wound obtained the day after surgery.

The effectiveness of laser LRIs or astigmatic keratotomy has yet to be established in the literature, although the precision of laser in creating incisions of the precise length and depth required suggests that the procedure should be more reproducible and reliable than manual methods. Several authors have shown reduction of astigmatism in patients who have undergone keratoplasty or in patients with a high degree of astigmatism with femtosecond laser arcuate keratotomy.<sup>39–42</sup> In addition, some authors have reported that femtosecond laser corneal relaxing incisions are effective in reducing corneal astigmatism during cataract surgery, and their long-term effectiveness should be evaluated.<sup>43</sup>

## CONCLUSIONS

Since the time of Charles Kelman's inspiration while in the dentist's chair (while having his teeth ultrasonically cleaned), progress in phaco technology and techniques has produced ever-increasing benefits, including more rapid visual rehabilitation and reduced dependence on contact lenses and glasses. Creative engineering and surgical ingenuity have acted synergistically to improve outcomes. Advances in technique and technology will continue to benefit our patients as we develop the exciting new future of small-incision cataract surgery.

**Fig. 5.11.9** Planned incision (A) with dotted line showing part to be opened at time of surgery with a surgical blade and optical coherence tomography (OCT) if incision the day after surgery (B).

# Manual Cataract Extraction

Frank W. Howes

# 5.12

**Definition:** Removal of crystalline lens by nonautomated or manual techniques.

## Key Features

- Diversity of techniques for optimal cataract patient outcomes.
- Intracapsular cataract extraction or large-incision full lens extraction.
- Extracapsular cataract extraction or large-incision nucleus expression cataract surgery.
- Small-incision manual nucleus expression lens surgery (“mininuc” technique).

## INTRODUCTION

The techniques of manual cataract surgery remain invaluable in the management of certain crystalline lens and zonular pathologies inappropriate for phacoemulsification (“phaco”).

The decision regarding the choice of procedure is based on a spectrum of factors related to the socioeconomic environment (equipment availability) and the operative experience (surgeon and team) on the one hand and to the ophthalmological condition of the patient on the other.

## Historical Issues

Manual cataract surgery techniques (initially intracapsular cataract extraction [ICCE] followed by extracapsular cataract extraction [ECCE]) have been the mainstay of cataract surgery for the majority of the last century. Much of the value of the manual techniques has been the lower costs and minimal instrumentation with which the surgery can be performed. These techniques provide excellent rehabilitation of blindness caused by cataract at the expense of only recovery time and stability of refraction over the first year.<sup>1</sup>

ICCE held favor over ECCE in view of the latter’s potential for complications (inflammation, iritis, phacoanaphylaxis, secondary membranes, glaucoma<sup>2</sup>) until the 1950s. The development of systems that provided simultaneous irrigation while aspirating was the key to the return of the extracapsular systems. These systems allowed for better removal of lenticular material (ECCE). These principles reached a high level of technological sophistication (and expense) in the phaco techniques. The attempts at cost containment led to the development of manual nucleus expression surgery through smaller incisions, or the so-called mininuc technique.<sup>3–6</sup>

## MANUAL (LARGE-INCISION) CATARACT SURGERY

These techniques require strict attention to wound construction for optimal optical outcome.

## Incision

An incision of 8–12 mm of arc length around the limbus (corneal, limbal, scleral, or a combination of all) is required to manually express the nucleus from the capsular bag in ECCE, whereas an incision of 12–14 mm around the limbus is required in ICCE. Variation in the incision position has a profound influence on the postoperative occurrence of cylindrical error.<sup>7</sup> The more corneal the section is placed, the stronger is the influence on the cylindrical error. The more scleral the section is placed, the less is the

cylindrical induction, particularly if a three-plane (Fig. 5.12.1), valve-type incision is utilized. Combinations of both scleral and corneal sections can be used to correct pre-existing cylindrical errors.<sup>8</sup> These sections can be rotated appropriately to reduce cylindrical error in any meridian.

When the incision is fashioned, the third plane of the incision (see Fig. 5.12.1) should be completed only when the anterior capsulectomy has been performed. This allows the anterior chamber to maintain depth, with or without viscoelastic material, while the anterior capsulectomy is undertaken. Once this is done, the internal incision may be completed.

## Wound Closure

During closure of a wound cut in the three-plane format, the sutures must not be overtightened; the edges are merely opposed (incisional gape)<sup>9</sup> (see Fig. 5.12.1). The valve effect of the incision seals the wound. In cases in which leakage is excessive, closure can be obtained by intracameral air.

Further opportunity for cylinder modification arises when sutures are removed. This allows controlled dehiscence of the wound. Dehiscence induces negative cylindrical effect at the meridian of the suture removal. A rough guide to timing suture removal is as follows:

- After 1 month, if major wound dehiscence is required to correct cylindrical error (3–6 diopters).
- After 2 months, if minor dehiscence is required to correct cylindrical error (2–3 diopters).
- At 3–6 months, to resume preoperative cylinder.
- After 6 months, to maintain surgically induced cylinder correction, if appropriate.

**Fig. 5.12.1** Three-plane scleral section. This incision is formed with the use of a sharp microsurgical knife for the initial vertical segment, followed by use of a curved dissecting blade to form the intralaminar section of the incision. The final vertical portion of the incision is best cut with corneal microscissors. Tissue elasticity produces the incisional gape evident.

**Fig. 5.12.2** Intracapsular delivery of the lens after it has been brought forward through the pupil with the cryoprobe. (A) The pupil constricts spontaneously as soon as the maximal diameter of the lens is through. In the lower left of the figure, the moist swab is shown as the swab and the lens are sliding. (B) The cornea has a concave surface, showing that the eye is soft without forward pressure from the vitreous body. The anterior chamber is reformed with a physiological solution. (From Roper-Hall MJ. Stallard's eye surgery. 7th ed. London, UK: Wright; 1989.)

## INTRACAPSULAR CATARACT EXTRACTION

### General Comments<sup>10</sup>

Currently, the need for ICCE is restricted to the need for removal of the entire crystalline lens. This is necessary when the zonular fibers are no longer present or when they are of insufficient strength to withstand the phaco process or to provide adequate stability for an intraocular lens.

Zonular dissolution, an essential step in the past, is thus unnecessary for today's indications for ICCE. The cryoprobe (tip freeze adherence driven by gaseous expansion) remains the most valuable tool for ICCE (Fig. 5.12.2).

### Specific Techniques

#### Iris Management

Full pupillary dilation is necessary for the lens to pass through. Posterior synechiae may need division or a miotic pupil may need stretching, but invariably the pupil is sufficiently elastic to permit passage of the lens. A small peripheral iridectomy should be cut at some stage in the procedure to avoid pupil block. Occasionally, a radial iridotomy (from peripheral iridotomy to pupil margin) is necessary for access to the lens surface for cryo-application and optimal "ice ball" formation. It is important to have a dry lens bed, free of both iris and cornea, for safe removal of the lens without collateral damage. (An assistant elevating the cornea with traction on a suture placed in mid-incision [incision as described above] will free the surgeon's nondominant hand to dry the lens and move the iris away with a microswab and operate the cryoprobe with the dominant hand to apply the "ice ball" and appropriate swaying traction to remove the lens.)

#### Vitreous Presentation or Prolapse

After careful removal of the lens, the vitreous face is likely to remain intact if unnecessary globe pressure is avoided. Should vitreous emerge from the entry wound, proper excision is necessary to avoid any vitreous traction syndrome. Vitrectomy may be necessary, depending on the intraocular lens of choice. Identification of prolapsed vitreous will be enhanced by injection of particulate triamcinolone.

#### Intraocular Lenses

Because the capsular bag has been removed, the choice of intraocular lens (IOL) support is limited to the angle, iris, or ciliary sulcus (fixated by suture). This should be done with ophthalmic viscosurgical device (OVD) protection.

An angle-supported lens must be fitted carefully to the individual chamber diameter so that it neither distorts nor moves for endothelial protection. An iris-supported lens, either anteriorly or posteriorly fixed, provides safe optical rehabilitation when adequate iris is available. Ciliary sulcus lens placement requires transscleral support by suture fixation and

is useful when there is either iris damage (e.g., from trauma) or trabecular damage (e.g., associated with glaucoma). Adequate vitreous clearance is a prerequisite in the case of all of these placement sites, particularly with ciliary sulcus fixation.

## EXTRACAPSULAR CATARACT EXTRACTION

Extracapsular surgery entails more steps compared with intracapsular surgery in that the capsular bag is left in the eye, held in position by zonular fibers. To initiate the process, a hole is made in the crystalline lens in a central position in the visual axis (anterior capsulotomy). The remainder of the process involves careful removal of the contents.

### Anterior Capsulotomy

The techniques of anterior capsulotomy have changed over the past 30 years.<sup>11</sup>

#### "Can Opener" Capsulotomy

The simplest type of capsular opening or capsulotomy is the "can opener" type, in which a number of very close, pinpoint perforations are created in a central, circular tract in the anterior capsule. Centripetal traction is placed on the central piece of capsule to create a tear along the perforations. The loose piece is then carefully removed. One advantage of this technique is the relative accuracy that can be achieved when visibility is poor (e.g., for a dense cataract with a poor red reflex or a very small pupil that requires the perforations to be made under the pupillary margin).

#### Linear Capsulotomy and Intercapsular Techniques

Linear capsulotomy techniques enable external expression while the anterior capsule is utilized to protect the corneal endothelium. In this method, a curvilinear incision is made in the upper third of the anterior lens capsule to create a slit or envelope opening into the lens capsular bag. After nucleus mobilization and expression and cortical material removal, the IOL can be inserted into the remaining capsular bag. The capsulotomy is completed by performing a continuous curvilinear capsulorhexis across the remaining capsule to complete the circular central opening.

#### Capsulorhexis

Capsulorhexis, or continuous curvilinear capsulotomy, is a quick and, once learned, easy technique for anterior capsule removal. It provides the best security for the IOL within the capsular bag.<sup>12</sup> The initial capsulotomy can be made centrally with a cystotome, or bent needle, or by utilizing the tip of a fine capsulorhexis forceps. Once the capsule has been opened, a piece of anterior capsule is grasped and torn in a circular manner, with continuous change of the tearing vectors to achieve the round opening (capsulotomy) in the anterior capsule.

### Size, Type, and Position of Capsulectomy

The capsulectomy needs to be large enough for the passage of the nucleus. The size of the nucleus is age dependent but can be modified by hydrodissection and hydrodelineation using an appropriate cannula.<sup>13</sup> If the nucleus is deemed too big for passage through the capsulectomy (e.g., after an unsuccessful hydrodelineation or after too small an initial capsulorrhexis), relaxing incisions in the capsulorrhexis are necessary to reduce the possibility of capsular dislocation and zonular damage during nucleus expression. During hydrodissection, if the anterior capsular opening is large enough, part of the equatorial rim of the nucleus can be expressed into the anterior chamber, then rotated into the anterior chamber and into the incision, and thus removed from the eye. OVD material between the corneal endothelial surface and the nuclear surface is necessary to prevent endothelial damage.

The size and shape of the capsulorrhexis can be varied by the surgeon. A large capsulectomy facilitates surgery, but when this exceeds approximately 6.5 mm in diameter, the capsulorrhexis becomes difficult to control because of the presence of the insertion of the zonules.<sup>14</sup> When the anterior capsular ridge is crossed, the danger of a peripheral radial irretrievable split<sup>15</sup> is possible (particularly if the anterior chamber is not kept deep; a shallow anterior chamber creates tension on the anterior zonular ligament). Peripheral splits are usually blocked by the zonular fibers, but unwanted posterior capsular tears may be caused by this mechanism.

### Nucleus Expression

The scleral lip of the incision should be depressed to allow the leading pole of the nucleus to present into the incision. Gentle pressure at the 180° opposing limbus then expresses the nucleus. The appropriate pressure may be applied with a broad-based instrument, such as a vectis or squint hook.

Alternatively, internal expression with the use of an irrigating vectis is effective, as long as the nucleus has undergone hydrodissection and partial hydroexpression. The space between the nucleus and the posterior capsule or cortex is opened with the irrigation function of the vectis. Viscoelastic material also is useful in defining and holding these spaces and in preventing posterior capsular and endothelial damage.

### Cortical Washout

The remaining cortex is removed using an irrigation–aspiration technique. The tip of the irrigation–aspiration cannula (Simcoe) should be kept in view to avoid unwanted capsular engagement. Difficulties can arise if the globe pressure causes the anterior chamber to become shallow, closing the fornix of the capsular bag. Partial closure of the wound and irrigation produces a deep and safe anterior chamber within which to work. Cleaning of the posterior capsule and removal of remaining resistant cortical remnants can be achieved by aspiration using a fine cannula with a polished tip.

### Intraocular Lens Insertion

Insertion of the IOL is performed under direct vision, with the second haptic inserted either by circular dialing of the IOL or by direct placement with the use of fine forceps.<sup>16</sup> When the capsular bag is damaged by complication, the sites of IOL placement become the same as those noted in the ICCE section. In some circumstances where sufficient capsular support still exists in spite of capsular damage, posterior chamber implantation can be considered (ciliary sulcus placement).

### Mininuc Technique<sup>3-6,17</sup>

#### Anterior Chamber Maintainer

An anterior chamber maintainer (ACM) (Fig. 5.12.3) is inserted through the clear cornea to the anterior chamber between the 4 o'clock and 8 o'clock positions, parallel to and near the limbus. The height of the infusion bottle determines the intraocular pressure (IOP). The continuous flow is responsible for the anterior chamber maintenance system.

#### Capsulorrhexis

The IOP is increased to 40 mm Hg (5.3 kPa). This pressure pushes the lens backward, which facilitates the formation of capsulorrhexis and prevents accidental radial capsule tear to the periphery.<sup>15</sup> A 5- to 6-mm capsulorrhexis is preferred.

#### Sclerocorneal Pocket Tunnel

The scleral entrance incision to the sclerocorneal pocket tunnel is frown shaped and 5 mm long and is placed 1 mm behind the limbus (Fig. 5.12.4).

**Fig. 5.12.3** Anterior chamber maintainer located at the 6 o'clock position, parallel and adjacent to the limbus, in clear cornea. The incision is made into the cornea with a stiletto 1.1 mm wide and beveled 1.5–2 mm.

**Fig. 5.12.4** Pocket tunnel dissection area and borders.

At both ends of the incision, perpendicular backward continuation incisions that are 1 mm long are cut. This extension helps accommodate the thickness of the nucleus as it passes through the tunnel. The tunnel is dissected anteriorly for 3–4 mm (1 mm in the sclera, 1 mm in the limbus tissue, and 2 mm in the clear cornea). Also, the scleral dissection is enlarged on both sides of the tunnel beyond the 1 mm backward scleral incision to make a pocket-like dissection (hence the term “pocket tunnel” rather than simply “tunnel”). The keratome internal incision is placed parallel to the curvature of the limbus and is 20% longer than the scleral outer incision. The pocket tunnel facilitates nucleus expression.

### Nucleus Manipulation

Hydrodissection is performed in two separate, anatomically distinct parts of the lens: the first just under the capsule and the second between the hard-core nucleus and the epinucleus.<sup>17</sup> Usually, the hydrodissection under the capsule partially moves the nucleus to the anterior chamber at the 12 o'clock position. If the nucleus does not move anteriorly, the hydrodissector cannula is lodged perpendicularly around the equator of the nucleus and then moved behind the nucleus. The positive IOP in the anterior segment pushes the posterior capsule away, creating a counterforce to the anterior movement of the hydrodissector cannula while the hard-core small nucleus is being separated from the epinucleus and the cortex. In this way, the smallest possible hard-core nucleus is isolated, to be delivered through the intact capsulorrhexis. At this stage, the nucleus is ready for expression.

### Nucleus Expression

A plastic glide (4 mm wide, 0.2 mm thick) is introduced through the tunnel under the nucleus. Slight pressure is induced on the glide at the inner limbal area, and the pressure is used to guide the nucleus that is to be engaged in the sclerocorneal pocket tunnel. This pocket is made to accommodate the nucleus at this stage. When the nucleus is well lodged

**Fig. 5.12.5** The nucleus is lodged in the pocket tunnel and hydroexpressed out of the eye. The glide is located behind the nucleus. External expression is performed on the glide away from the external incision of the pocket tunnel.

in the pocket and no leakage of balanced salt solution (BSS) is observed, slight scleral pressure is induced. The further the nucleus is expressed (Fig. 5.12.5), the more backward is the location of the scleral pressure. If the external pressure on the sclera is located near the internal incision throughout, an area of leakage is created rather than prevented, and nucleus expression cannot be completed. The IOP during nucleus expression is 40–45 mm Hg (5.3–6.0 kPa), helping hydroexpression of the nucleus.

### Cortex Removal and Intraocular Lens Implantation

Cortex removal and IOL implantation are facilitated by the deep anterior chamber formation induced by the ACM system. Insertion of the IOL is performed under direct vision, in a similar manner to ECCE, as described above. With a smaller incision than those in both ECCE and ICCE, the techniques of foldable lens insertion, as used in phaco surgery, can be employed.

## COMPLICATIONS

Complications of cataract surgery tend to be similar among all of the techniques used, although the incidences of the complications of the different techniques vary (Box 5.12.1). In the majority of cases, these complications occur in relation to capsular damage, with consequential anterior segment vitreous and iris involvement, occasionally involving the incision as well. Poor technique may lead to inflammatory conditions when lens nucleus material has not been completely removed or incisions have been closed poorly. Complications tend to be sequential, increasing the importance of producing a good result at the first surgery. Experience in each technique minimizes complications.

## DISCUSSION

The drive toward smaller-incision surgery has continued, and with new techniques of smaller-incision nuclear expression surgery combined with

### BOX 5.12.1 Complications of Cataract Surgery

Optical power aberrations (sphere and cylinder)  
Capsule rupture without vitreous loss  
Capsule rupture with vitreous loss  
Vitreous capture in incisional wound  
Iris prolapse  
Iris capture in incisional wound  
Nucleus loss into the posterior segment  
Intraocular lens loss into the posterior segment  
Inability to primarily implant intraocular lens because of the above  
Glaucoma (aphakic, inflammatory, malignant, pupil block)  
Corneal endothelial damage  
Chronic inflammatory disease  
Cystoid macular edema  
Retinal detachment  
Hypotony  
Choroidal edema and effusion  
Choroidal hemorrhage  
Infection

the introduction of anterior capsule staining techniques, advanced grades of cataract surgery have been performed successfully.<sup>18</sup> These techniques continue to prove useful in developing countries, where cost constraints are a factor in the delivery of sight-saving cataract surgery.<sup>19</sup> The results compare favorably with modern phaco surgery.<sup>20</sup>

**Definition:** Cataract surgery simultaneously combined with other ocular surgery.

## Key Features

- Combined surgery for glaucoma and cataract is a valid option in management.
- Minimally invasive glaucoma surgery (MIGS) frequently is combined with cataract surgery.
- Descemet's stripping automated endothelial keratoplasty (DSAEK), rather than penetrating keratoplasty, combined with cataract surgery is now the treatment of choice for coexisting cataract and corneal endothelial disease.
- Refractive outcome from combined DSAEK–Descemet's membrane endothelial keratoplasty (DMEK) and cataract removal is much more predictable than with penetrating keratoplasty.
- Combined phacovitrectomy, rather than sequential surgery, is used increasingly for some conditions, such as macular hole and pucker, even when pre-existing lens opacities are minimal, especially in those older than ages 50–60 years.

## INTRODUCTION

Cataract develops mainly as a response to aging but also as a result of chemical or biological insults to the eye. The conditions that are commonly associated with cataract and that lend themselves to combined surgical approaches are glaucoma, corneal opacity, effects of penetrating trauma, and vitreoretinal disorders.

## COMBINED GLAUCOMA SURGERY

### Overview

The prevalence of significant cataract in people ages 65–74 years is greater than 20%, and the prevalence of chronic glaucoma is about 4.5% in people over age 70 years.<sup>1,2</sup> The 5-year incidence of nucleus cataract in people with open-angle glaucoma and older than 50 years is estimated to be 20%. Patient adherence to treatment with topical glaucoma medication, the most common form of glaucoma treatment, is low.<sup>3</sup>

For these reasons, combining cataract surgery and glaucoma surgery in a single operation appears to be a valid management option. There has been a rapid expansion in recent years in the number of devices, implants, and techniques that are less invasive and are safer than those used in traditional glaucoma surgery. In minimally invasive glaucoma surgery (MIGS), these techniques are increasingly being combined with cataract surgery.

An important consideration is that cataract surgery alone results in an intraocular pressure (IOP) drop of up to 5 mm Hg in patients with glaucoma.<sup>4</sup> Complications after glaucoma surgery may increase the risk of an adverse outcome.<sup>5</sup>

## Trabeculectomy and Cataract Surgery

Phacoemulsification (“phaco”) combined with glaucoma surgery probably produces better IOP control with fewer complications compared with manual extraction plus glaucoma surgery, although there are no large well-controlled, randomized studies on this.<sup>4,6,7</sup> However, IOP reduction and subsequent control seem to be less effective with combined surgery than with trabeculectomy alone—possibly as a result of more prolonged breakdown of the blood–aqueous barrier associated with cataract surgery.<sup>8</sup> When combined surgery is considered, a single-site approach may be less time consuming, but a two-site approach allows the surgeon to use the familiar temporal clear corneal approach to the cataract. There is ongoing debate as to whether a single-site or two-site approach gives better control, and several studies have reported no significant difference in the IOP-lowering effect.

## Nonpenetrating Glaucoma Surgery and Cataract

Nonpenetrating glaucoma surgery (deep sclerectomy with or without viscocanaloplasty) can be combined with phaco. Some studies have reported that these techniques are as effective as trabeculectomy when combined with phaco,<sup>9–11</sup> but longer-term studies are required to support this claim.

## Minimally Invasive Glaucoma Surgery

MIGS is potentially less traumatic and has a higher safety profile compared with conventional surgery. These techniques should involve an ab interno conjunctiva-preserving approach and consequently produce a modest reduction in IOP. Often combined with phaco, in which case it is termed “phacoplus,” the aim of surgery is to reduce the need for topical medications in patients with mild-to-moderate glaucoma. Most studies performed in patients who undergo MIGS in combination with phaco. Because of the large number of patients in this group, the potential market for these products is large. Few trials of sufficient quality exist at present to make firm recommendations. Reviews of the literature are cautious at best.<sup>12,13</sup> These treatments do offer alternatives to patients with glaucoma, and if studies demonstrate clinical effectiveness over the long term, these techniques may become more universally adopted.

## Aqueous Shunts

Aqueous shunts, such as the Baerveldt or Ahmed valve, are indicated in the treatment of more complex refractory glaucoma cases where surgery is required. Phaco can be performed effectively at the time of shunt surgery, although the decision to combine the two procedures has to be made on a case-by-case basis because only small retrospective case series reports are available.<sup>14</sup>

## Outcomes

Phaco surgery can be incorporated into many glaucoma procedures. IOP reduction following phacotrabeculectomy is greater than that following cataract surgery alone, although not as great as following trabeculectomy alone.<sup>15</sup> Increasingly, the role of MIGS may offer patients with cataract and early glaucoma the option not to use topical medication following combined surgery, although further study on this is required.

**Fig. 5.13.1** (A) Patient with combined corneal and lens opacities. This degree of corneal opacity demands an “open sky” approach to cataract removal. (B) Here, an iris expander device and an “open sky” technique of cataract extraction are used. (C) “Open sky” cataract extraction performed. (D) Combined cataract extraction with intraocular lens (IOL) implantation and penetrating keratoplasty.

## LENS SURGERY COMBINED WITH KERATOPLASTY

### Historical Review

Anterior or posterior lamellar corneal surgery is now much more common compared with penetrating keratoplasty (PKP). Eyes that require keratoplasty often have an associated increased risk of cataract because of the underlying pathology (Fig. 5.13.1); this includes corneal perforation as a result of trauma or infection. Also, age-related corneal degeneration, such as Fuchs’ corneal degeneration, often coexists with age-related cataract. These factors resulted in the development of a variety of techniques for combined primary cataract surgery and keratoplasty (“triple procedure”), or IOL exchange combined with keratoplasty. Combined cataract surgery and lamellar corneal surgery is often referred to as the “new triple procedure.”

### Surgical Options

A retrospective analysis of eyes that underwent PKP for Fuchs’ endothelial dystrophy, with an average follow-up period of 6 years,<sup>16</sup> showed an incidence of significant cataract in 75% of patients over 60 years of age. In those who subsequently required lens surgery, 13% lost transplant clarity postoperatively. Two recent reports following Descemet’s stripping endothelial keratoplasty (DSEK) showed the presence of cataract in 40% at 1 year in one study and cataract extraction rate of 31% and 55% at years 1 and 3, respectively, in patients over 50 years of age.<sup>17,18</sup> Similarly, studies following Descemet’s membrane epithelial keratoplasty (DMEK) showed a 76% progression of cataract.<sup>19</sup> Following DSEK/DSAEK the endothelial cell loss rate can be as high as 56% in the first year,<sup>20</sup> although with standardized technique, the endothelial cell loss has been reduced to less than 35%. In patients undergoing DMEK, the endothelial cell count loss at 1 year is in

the range of 25%.<sup>19</sup> Multiple reports have suggested that combined cataract surgery and endothelial grafts (DSAEK and DMEK) were not associated with any increased complication rate or endothelial cell loss.<sup>21,22</sup> Therefore, an argument exists for not subjecting such a cornea to multiple surgeries. The decision in individual cases depends on the balance of the risks and benefits. One key decision for the clinician is whether it is possible to determine if the main barrier to good vision is the cornea or the lens. Another is the likelihood of development of frank decompensation if keratoplasty is not carried out. A combined approach may be the best choice in either circumstance.

Choice of IOL depends on individual circumstances. In the event that cataract surgery is part of the primary procedure, a standard IOL can be placed in the capsular bag. If sufficient capsular and/or zonular support exists, then the best option is a capsule or sulcus-placed posterior chamber IOL. If adequate support is not available, then the choice is a posterior chamber IOL, either transclerally sutured or iris sutured.<sup>23,24</sup>

Biometry and IOL power calculation is problematic if PKP or lamellar keratoplasty is combined with cataract surgery. The refractive impact of DSEK, however, is reasonably consistent, with a hyperopic shift of 0.75–1.5 D,<sup>25</sup> although this is much less with thinner grafts. With the use of DMEK, where little or no stroma is transplanted, the surgery causes even less change in the refractive power.<sup>26</sup>

### Specific Techniques

The techniques of keratoplasty are dealt with elsewhere. A significant recent trend is toward either anterior or posterior lamellar keratoplasty, and significant benefit is obtained by the cataract surgeon in these closed-chamber techniques. The ongoing audit of keratoplasty conducted by the Corneal Graft Registry of the National Health Service (NHS) – Blood and Tissue, in the United Kingdom, has shown that during 2010, 26%

See clip:  
5.13.1

of the surgeries performed were deep posterior lamellar keratoplasty, 15% were deep anterior lamellar keratoplasty (DALK), and 56% were DSEK, with the number of endothelial keratoplasty procedures increasing.

Phaco surgery can be difficult because of the poor visibility as a result of the corneal disease. Selected cases with stromal opacity (see Fig. 5.13.1A) may be suitable for a routine phaco procedure after DALK and use of an ophthalmic viscosurgical device in the bed to restore anterior chamber and capsule visibility.<sup>27</sup> In cases of endothelial disease where the stromal clarity is reasonable, a combined phaco with DSEK/DMEK is now the preferred technique (Video 5.13.1). This offers much quicker visual rehabilitation and more predictable refractive outcome than combined PKP and phaco.<sup>28</sup>

Such an approach is not always possible, and “open sky” removal of the lens may be required. The altered anterior-chamber and lens-iris diaphragm dynamics, abnormal light reflexes present in the “open sky” situation (see Fig. 5.13.1),<sup>29</sup> and difficulty in controlling the anterior and posterior capsule increases the risk of surgical complications. Capsulorhexis can be difficult because of decreased anterior pressure caused by the “open sky.” Careful use of scissors can be of help. The nucleus is expressed manually after thorough hydrodissection. Manual irrigation-aspiration of the cortex is carried out with the use of a cannula, such as the Simcoe cannula.

When specific endothelial keratoplasty techniques are combined with cataract surgery, certain additional risks, such as pupil abnormalities and lens subluxation or dislocation, arise either because of the effect of the air tamponade or anterior chamber depth modulation needed in these surgeries.

## Complications

Apart from the possible inherent complications of keratoplasty, the combined procedure carries an increased risk of cystoid macular edema. Other complications of combined procedures are the variability of refractive outcome and the delayed visual rehabilitation compared with straightforward cataract surgery. Weighed against this, however, is the additional risk of graft failure inherent in the alternative of a two-stage procedure.

## Outcomes

There are currently no definitive studies providing hard evidence of the benefit of one approach over another, but with the development of standardized techniques of corneal graft surgery, the new triple procedure shows very similar results to the two-stage approach.

## COMBINED PHACOVITRECTOMY

### Introduction

Both age-related cataract and secondary cataract are a common feature in many patients with vitreoretinal disorders. The widespread acceptance of phaco in the late 1980s and 1990s and the availability of combined phaco and vitrectomy machines with single cassettes offered the possibility of efficient combined surgery, with secure wound construction and stable intracapsular IOL fixation. Although pars plana fragmatome lensectomy is still performed in specific scenarios, combined phaco with IOL implant and vitrectomy (phacovitrectomy) is now an established technique to deal with concomitant cataract when vitrectomy is performed. Studies have shown that combined phacovitrectomy can be carried out with low morbidity and good results.<sup>30</sup> As confidence with the technique has grown, indications for combined surgery have expanded.

### Indications and Advantages Over Sequential Noncombined Surgery

When first introduced, phacovitrectomy was reserved for cases where cataract precluded an adequate fundal view during vitrectomy surgery. However, phacovitrectomy now is increasingly used when lens opacities are mild or even nonexistent, particularly in patients over 50–60 years of age.<sup>31</sup> In these cases, cataract surgery is not necessary to successfully complete the vitrectomy but is done to avoid the need for subsequent cataract surgery and hasten visual recovery. Vitrectomy surgery, particularly in the age group of over 50 years, often results in the development of significant lens opacities, especially if long-acting gases are used, as in macular hole surgery.<sup>32,33</sup>

Phacovitrectomy in these situations offers a number of advantages over vitrectomy followed by subsequent cataract surgery in two steps. Only one operation is needed, avoiding the surgical difficulties and morbidity associated with cataract extraction following vitrectomy. These include small pupil size, deep anterior chamber with reverse pupil block, and increased mobility of the lens-iris diaphragm with an increased risk of posterior capsule tears.

Combining phaco and vitrectomy also improves postoperative retinal visualization, allowing accurate retinal assessment and treatment, and visual recovery is not delayed by subsequent cataract development. Phacovitrectomy allows more complete anterior vitrectomy and access to the anterior retina and vitreous base without the risks associated with lens touch.<sup>34</sup>

## Disadvantages

Macular hole and macular pucker are the most common clinical scenarios where “nonessential,” optional phacovitrectomy is considered because of the high frequency of cataract formation after surgery in these cases in the age group affected. However, not all patients are ideal candidates for phacovitrectomy. For some patients, vitrectomy, followed by sequential cataract surgery, if needed, is a better option. In patients with diabetes, lens opacities following vitrectomy are paradoxically less common than in those without diabetes.<sup>35</sup> Among patients with diabetes, there seems to be a higher incidence of posterior synechiae, posterior capsule opacity, and inflammatory anterior uveitis following phacovitrectomy, especially if retinopathy is very active; a large amount of intraoperative laser is needed, or gas tamponade is used.<sup>36</sup> Therefore, although phacovitrectomy is frequently carried out successfully in patients with diabetes who have significant lens opacities,<sup>37</sup> these patients are not always ideal candidates for phacovitrectomy.

The absence of accurate preoperative biometry secondary to vitreoretinal pathology, with variable axial length measurements and fixation, also could be regarded as a relative contraindication to nonessential phacovitrectomy. Fellow-eye measurements can be used, but incorrect axial length estimations will result in errors in IOL choice and potentially significant unplanned ametropia. Similarly, scleral buckling and use of silicone oil alter the final refractive outcome in an unpredictable way. Phacovitrectomy in eyes with elevated maculae, as occurs with epiretinal membrane and macular holes, has been reported to be associated with a myopic shift in the planned refraction. This is most likely to be related to measuring a short axial length preoperatively with the use of ultrasonography, but it also may be related to gas-induced, anterior chamber depth changes.<sup>38</sup> The use of partial coherence interferometry (PCI) to measure axial length (which uses the retinal pigment epithelium [RPE] reflection, rather than the inner retinal surface) can overcome some of these errors.<sup>39</sup> However, if PCI is used in eyes with thickened maculae, the graphical display should be inspected. If the inner retinal reflectivity is high (e.g., with a dense epiretinal membrane), the device can occasionally interpret this reflective peak as the RPE. In this situation, the graph cursor can sometimes be adjusted to the lower RPE peak manually.<sup>40</sup> Details on adjustment and other potential errors in measurement can be found in manufacturers’ device manuals. If axial length is measured by using ultrasonography, aiming approximately 0.5 dioptres hypermetropic or correcting for the preoperative macula thickening based on optical coherence tomography (OCT) measurements, can reduce the effect.<sup>38,41</sup>

Similarly, with macula involving retinal detachment, care needs to be taken to ensure that the true axial length is measured rather than from the detached retina. Sometimes, the scan cursor can be manually changed to the RPE peak with optical biometry, but if any doubt exists, the true axial length should be measured by using combined vector-A/B-scan biometry.<sup>42,43</sup>

## Specific Techniques

Lens surgery can be carried out successfully via either a clear corneal incision (CCI) or scleral tunnel incision. If valved sclerostomy ports are used, they can be inserted prior to phaco to avoid the risk of wound leak during later insertion. If nonvalved ports are used, then all but the infusion port may be more optimally placed after phaco to avoid loss of vitreous cavity fluid and exacerbated lens iris diaphragm retropulsion syndrome, especially in already vitrectomized eyes.<sup>44</sup> If a corneal incision is used, then the tunnel should be kept relatively short to avoid interference with the posterior segment view. Similarly, temporal incisions are less axial and less likely to interfere with the fundal view than superior ones. A suture can be

See clip:  
5.13.2

used to secure the wound to avoid wound leak during scleral indentation (Video 5.13.2).

Posterior segment intraocular gas pressure can cause significant problems in phacovitrectomy. Anterior displacement of the optic of the IOL by posterior gas pressure can lead to optic capture by the iris. Similarly, displacement of the anterior capsule onto the iris can lead to postoperative posterior synechiae formation. There are some possible strategies to reduce the incidence of these problems. Sustained postoperative dilatation should be avoided, but some clinicians use short-acting mydriatics to discourage synechiae formation. Capsulorrhexis size should be large enough to avoid problems with rhexis phimosis but should aim to just overlap the optic edges by 0.5 mm to hold the optic posteriorly. Capsulorrhexis can occasionally be difficult in eyes with vitreous hemorrhage and no red reflex. In these cases, capsule staining and/or use of the endoillumina-tor in the anterior chamber can facilitate visualization. Alternatively, some vitrectomy can be carried out first, if possible, to improve the red reflex before rhexis is undertaken. IOL optic diameter should be large to reduce the risk of optic capture. Lenses with broad haptic fixation offer the advantages of avoiding optic capture and superior IOL centration.

IOL insertion can be performed either before or after vitrectomy is completed. Peripheral vitreous base view can be impaired in pseudophakic eyes, and there is an argument for withholding IOL insertion until after the posterior segment surgery has been completed. IOLs with rounded, tapering edges and a gradual reduction in optic power offer advantages for “trans-IOL” vitrectomy by avoiding the occurrence of “jack-in-the-box” prismatic effects when viewing the posterior segment through the edge of the IOL. Posterior capsule opacity appears to be more common after phacovitrectomy, and primary capsulectomy with the vitrectomy cutter can be performed to avoid another threat to delayed visual recovery.<sup>45</sup> Acrylic folding IOLs have several advantages over silicone IOLs with less IOL condensation during fluid–air exchange and also reduced possibility of silicone oil adherence if oil is subsequently used.

## Conclusion

Phacovitrectomy is an effective technique to allow combined cataract extraction and vitrectomy. Its use is now being extended to patients with

minimal lens opacities before they undergo, for example, macular hole surgery, to avoid delaying visual recovery secondary to postoperative cataract.

# Cataract Surgery in Complex Eyes

Jesse M. Vislisl, Gary S. Schwartz, Stephen S. Lane

# 5.14

**Definition:** Cataract surgery in eyes with other pathologies.

## Key Features

- Zonular integrity is evaluated at the slit lamp preoperatively by assessing for lens decentration, phacodonesis, and iridodonesis.
- Uveitis may complicate cataract surgery as a result of poor dilation, posterior synechiae, zonular laxity, and exaggerated postoperative inflammation.
- Preoperative endothelial cell density less than 1000/mm<sup>2</sup>, central corneal thickness greater than 640  $\mu$ m, and corneal epithelial edema indicate increased risk for postoperative corneal decompensation in patients with Fuchs' corneal dystrophy.
- Femtosecond laser-assisted cataract surgery may have distinct advantages for certain complex eyes because of ease in capsulorhexis creation, assistance with nucleofractis, and reduced postoperative endothelial cell loss.

## Associated Features

- A large capsulorhexis ( $\geq 5.5$  mm in diameter) facilitates removal of nuclear fragments and reduces postoperative anterior capsular phimosis in the setting of zonular laxity.
- Areas of weakened zonules may be stabilized intraoperatively and postoperatively by using capsular hooks, capsular tension rings, and capsular tension segments.

## INTRODUCTION

Modern cataract surgery can normally be performed with minimal anesthesia, manipulation of ocular tissue, and postoperative morbidity. Although most surgeons perform routine surgery using the same basic techniques for all patients, in some circumstances, the surgical technique must be altered because of specific preoperative conditions in complex eyes.

## ZONULAR INSTABILITY

When cataract surgery and intraocular lens (IOL) placement are planned for a patient with history of ocular trauma, intraocular surgery, pseudo-exfoliation syndrome, or systemic conditions associated with zonulopathy (e.g., Marfan's syndrome), it is important for the surgeon to evaluate the status of the zonules. Zonular instability increases the risk of intraoperative complications and the likelihood of IOL subluxation postoperatively.<sup>1,2</sup>

Zonular integrity may be evaluated at the slit lamp preoperatively by looking for the presence of lens decentration, phacodonesis, or focal iridodonesis. This may be facilitated by having the patient quickly shift the direction of gaze or by gently shaking the slit lamp table with a fist. When necessary, it often is possible to directly visualize the zonular ligament fibers by using a gonioscope. If a patient has a history of ocular trauma, the eye should also be examined for iridodialysis and vitreous in the anterior chamber, either of which makes zonular dehiscence likely.

During surgery, care must be taken to preserve as many of the remaining supporting zonules as possible. If discrete areas of zonular dehiscence are present, a cohesive ophthalmic viscosurgical device (OVD) may be used to force a dispersive OVD into the area of zonular loss and prevent vitreous prolapse into the anterior chamber. The anterior capsule may initially dimple under the cystotome tip in the presence of zonular laxity, rather than being immediately punctured. If difficulty is encountered when beginning the anterior capsular tear, two 27-gauge needles may be used in

a crossing fashion to create countertraction and assist with initiation of the rhexis. After the capsulorhexis is begun, pseudo-elasticity of the capsule may be experienced because of the reduction in counterresistance offered by the zonules to oppose the tearing forces applied by the surgeon.<sup>3</sup> In cases of marked zonular loss, capsular hooks or retractors may be utilized to stabilize the bag and facilitate completion of the rhexis.<sup>4</sup> If these are unavailable, nylon iris fixation hooks can be used in a similar manner, although the tips may tend to inadvertently tear the capsule. After starting the rhexis, the surgeon gently retracts the capsular edge with hooks in the direction of the area of dehiscence. After the rhexis is completed, the hooks may be left in place while hydrodissection and phacoemulsification ("phaco") are performed. A large rhexis (at least 5.5 mm in diameter) is made to facilitate removal of nuclear fragments and prevent postoperative anterior capsular phimosis. Careful and complete hydrodissection is performed so that the nucleus rotates easily within the capsular bag with minimal zonular stress. Bimanual rotation may be utilized to further reduce zonular stress by simultaneously rotating the nucleus using two instruments located 180° apart.

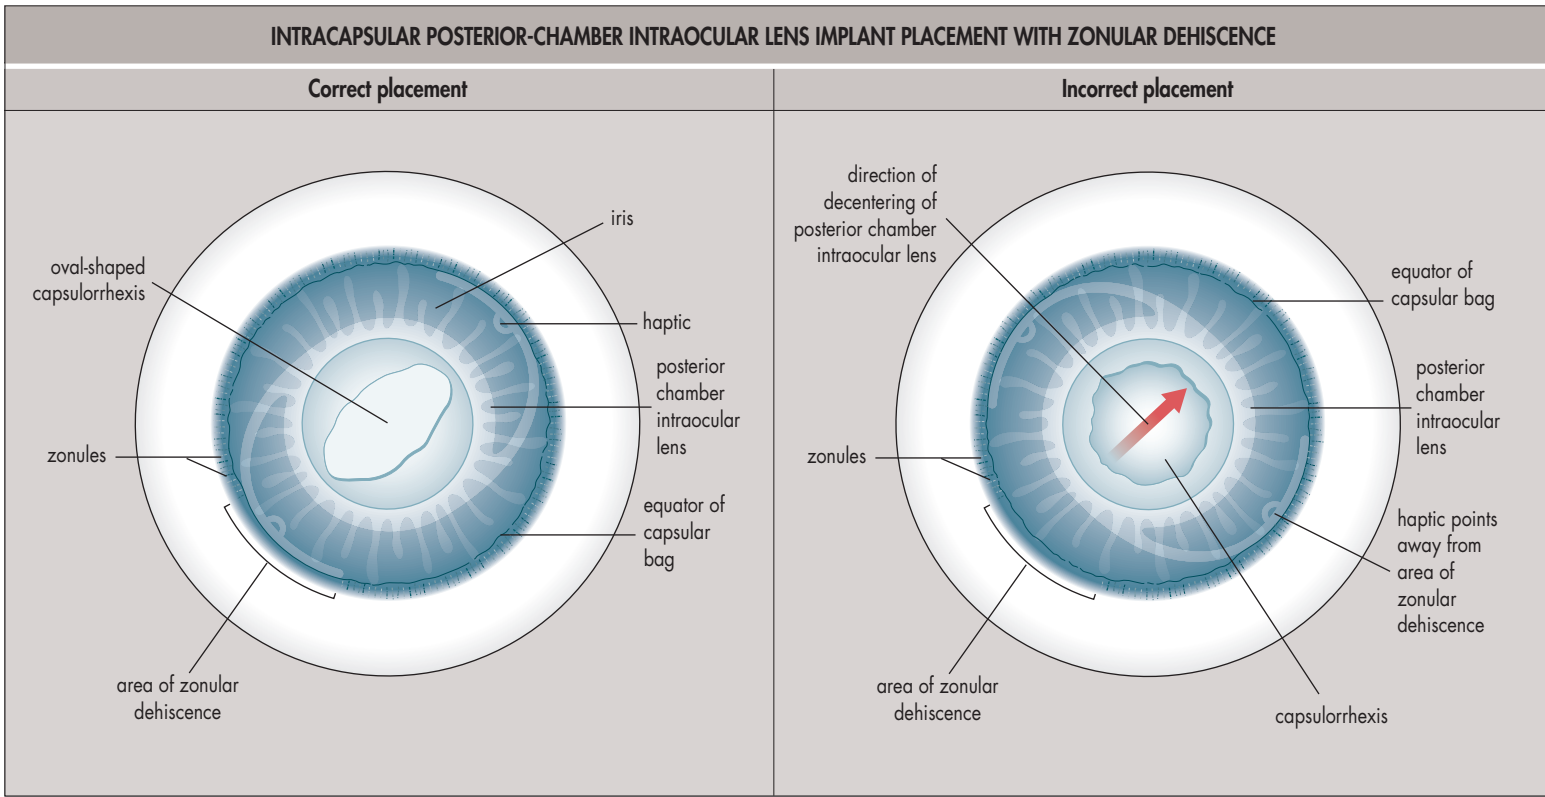

A horizontal chop technique is preferable for nuclear disassembly in situations of zonular laxity because it causes minimal strain on the zonular fibers. If grooving is performed within the capsular bag, the main incision should be created in a position so that the phaco needle carves toward the area of dehiscence to prevent induction of forces that extend the area of zonular loss. If the surgeon feels that zonular support is inadequate for intracapsular manipulation, the nucleus may be prolapsed from the capsular bag, and phaco can be performed within the anterior chamber.

Once the nucleus and epinucleus have been removed, cortical cleanup must be performed delicately. Stripping the cortex in tangential fashion with forces perpendicular to the radial zonular fibers has been shown to exert reduced force on the zonule.<sup>5</sup> With the nucleus removed, the capsular bag is floppier in nature, and the area of the dehiscence may be drawn toward the aspiration tip. In such cases, the surgeon may have more control when the irrigation and aspiration ports are separated to perform bimanual irrigation-aspiration. In this way, the irrigation tip can be used to hold back the capsular fornix of the area of dehiscence while the aspiration tip safely removes cortex.

After complete removal of the cataract, an appropriate IOL must be selected. Whenever possible, the IOL is placed within the capsular bag. Intracapsular IOL placement without a capsular tension segment or ring may be appropriate for patients who have small areas of zonular dehiscence. In such cases, a three-piece posterior-chamber intraocular lens (PCL) should be placed so that one of the haptics is oriented toward the area of dehiscence, thus extending the bag in that direction (Fig. 5.14.1). If the haptics are rotated so that they are 90° away from the dehiscence, the optic is more likely to decenter in a direction away from the area of dehiscence.

Mild, diffuse, zonular laxity and zonular dehiscence up to 4 clock hours may be managed by placing a capsular tension ring within the capsular bag. Areas of dehiscence greater than 4 clock hours may be managed by using capsular tension segments to provide additional capsular support. Capsular tension segments and some tension rings, such as the Cionni ring, have eyelets to allow fixation to the scleral wall with a polypropylene or Gore-Tex suture.<sup>6</sup> These devices are left in place postoperatively and have been shown to help expand and center the capsular bag, thus preventing the lens implant from migrating away from areas of zonular dehiscence.

If capsular support is felt to be inadequate for intracapsular lens placement, an alternative technique should be utilized (Table 5.14.1). A sulcus-supported PCL can be placed so that the haptics are 90° away from the area of dehiscence (Fig. 5.14.2). This orientation prevents the haptics from slipping posteriorly into the vitreous chamber. If a continuous curvilinear capsulorhexis has been performed, it is advantageous to prolapse

**Fig. 5.14.1 Intracapsular Posterior-Chamber Intraocular Lens (PCL) Implant Placement With Zonular Dehiscence.** With correct placement within the capsular bag, one haptic is positioned toward the area of dehiscence to extend the capsule peripherally, stabilize the region, and maintain optic centration. Note that the capsulorrhexis is ovoid in shape because it has been pulled by the haptic in the direction of the dehiscence. With incorrect placement, the haptics are oriented 90° away from the dehiscence. In this situation, the PCL may decenter away from the area of dehiscence in the direction of the arrow.

TABLE 5.14.1 Options for Intraocular Lens Placement After Cataract Extraction			
Procedure	Optic Position	Haptic Position	Haptic Fixation
Intracapsular posterior-chamber intraocular lens (PCL) implant	Capsular bag	Capsular bag	Capsular bag fornices
Intracapsular PCL with reverse optic capture*	Posterior chamber	Capsular bag	Capsular bag fornices
Sulcus-supported PCL	Posterior chamber	Ciliary sulcus	Ciliary sulcus
Sulcus-supported PCL with optic capture*	Capsular bag	Ciliary sulcus	Ciliary sulcus
Transscleral fixated PCL	Posterior chamber	Ciliary sulcus	Trans-scleral fixation
Iris-sutured PCL	Posterior chamber	Ciliary sulcus	Iris sutures
Anterior chamber lens	Anterior chamber	Anterior chamber	Anterior chamber angle
Aphakia	None	None	None

\*The “optic capture” and “reverse optic capture” techniques require an appropriately sized and intact continuous curvilinear capsulorrhexis.

the optic posteriorly into the capsular bag while the haptics remain in the sulcus. This technique often results in more stable optic centration in the presence of zonular dehiscence.

If insufficient capsule is present to support both haptics, a PCL may be sutured to the iris or transsclerally fixated by using suture or other means (Fig. 5.14.3).<sup>7,8</sup> Since transscleral and iris fixation procedures are technically difficult to perform, some surgeons may opt for placement of an anterior chamber lens instead. Modern anterior chamber lenses have proven to be safe,<sup>9</sup> although many surgeons still prefer to keep the IOL as close as possible to the physiological location of the natural crystalline lens.

Femtosecond laser-assisted cataract surgery (FLACS) may have considerable advantages in patients with zonular laxity. In this setting, creation of the rhexis is performed by using disruptive laser energy, rather than tearing forces, and thus is not dependent on countertraction from healthy zonules. In addition, much of the nucleofractis technique is performed atraumatically by the laser and thus further zonular loss from the mechanical action of the phaco tip is avoided.

## UVEITIS

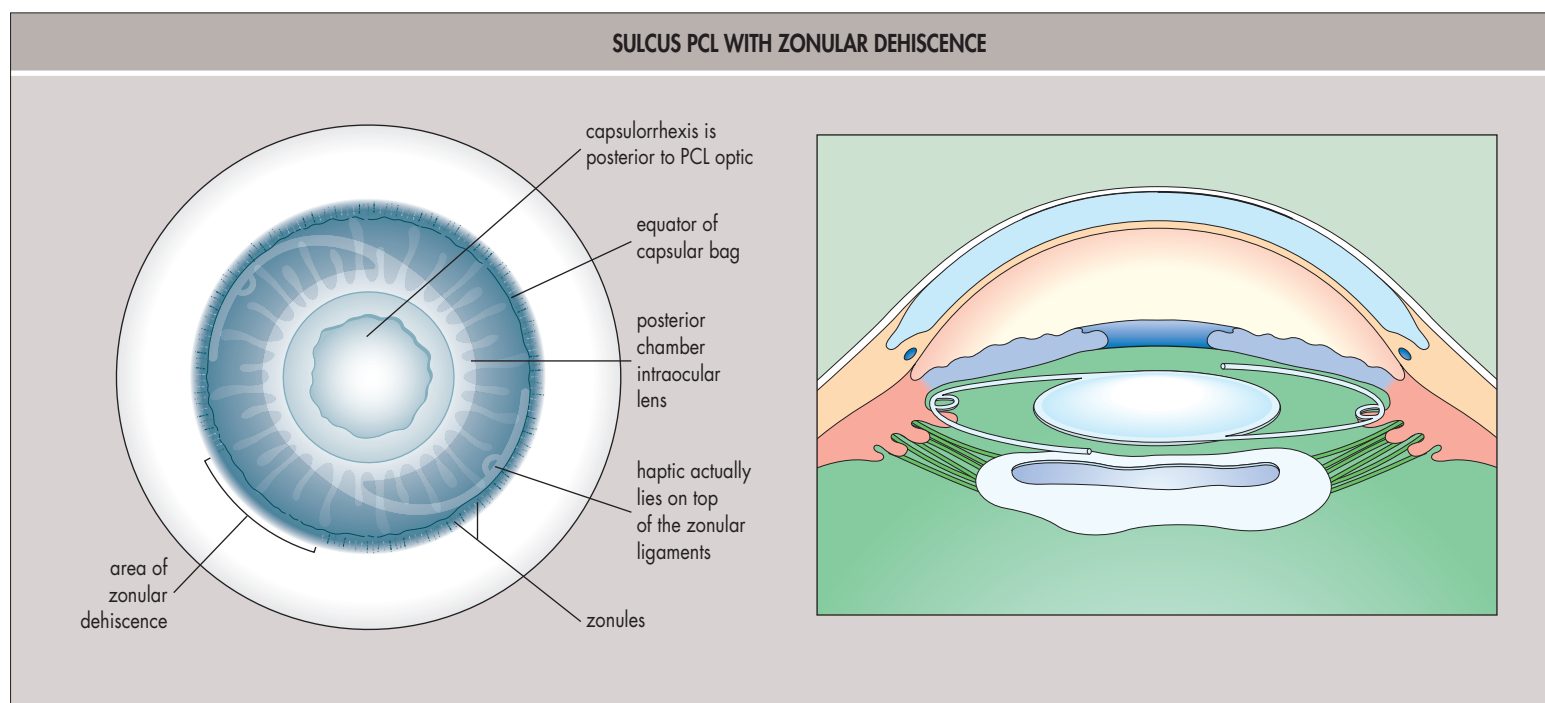

Cataract extraction with IOL insertion in patients with uveitis is often made more difficult because of poor dilation, posterior synechiae, zonular laxity, and higher levels of postoperative inflammation. If possible, a patient should not undergo surgery until the uveitis has been quiescent for at least 3 months. Even so, patients with a significant history of uveitis should receive oral prednisone 10 mg/kg daily for up to 1 week prior to surgery followed by a 2- to 3-week taper. In addition, select patients may benefit from intravenous methylprednisolone sodium succinate 125–250 mg during the surgery. Patients with chronic uveitis secondary to herpes simplex or varicella-zoster virus infections should be treated with perioperative oral antivirals at full treatment doses.

Small-incision phaco is the procedure of choice for patients who have a history of uveitis.<sup>10</sup> The smaller incision results in less iris manipulation than large-incision nucleus expression and results in less postoperative inflammation and faster healing. In addition, creating the wound in the avascular clear cornea results in less inflammation compared with a scleral tunnel incision because the limbal and conjunctival blood vessels are spared.

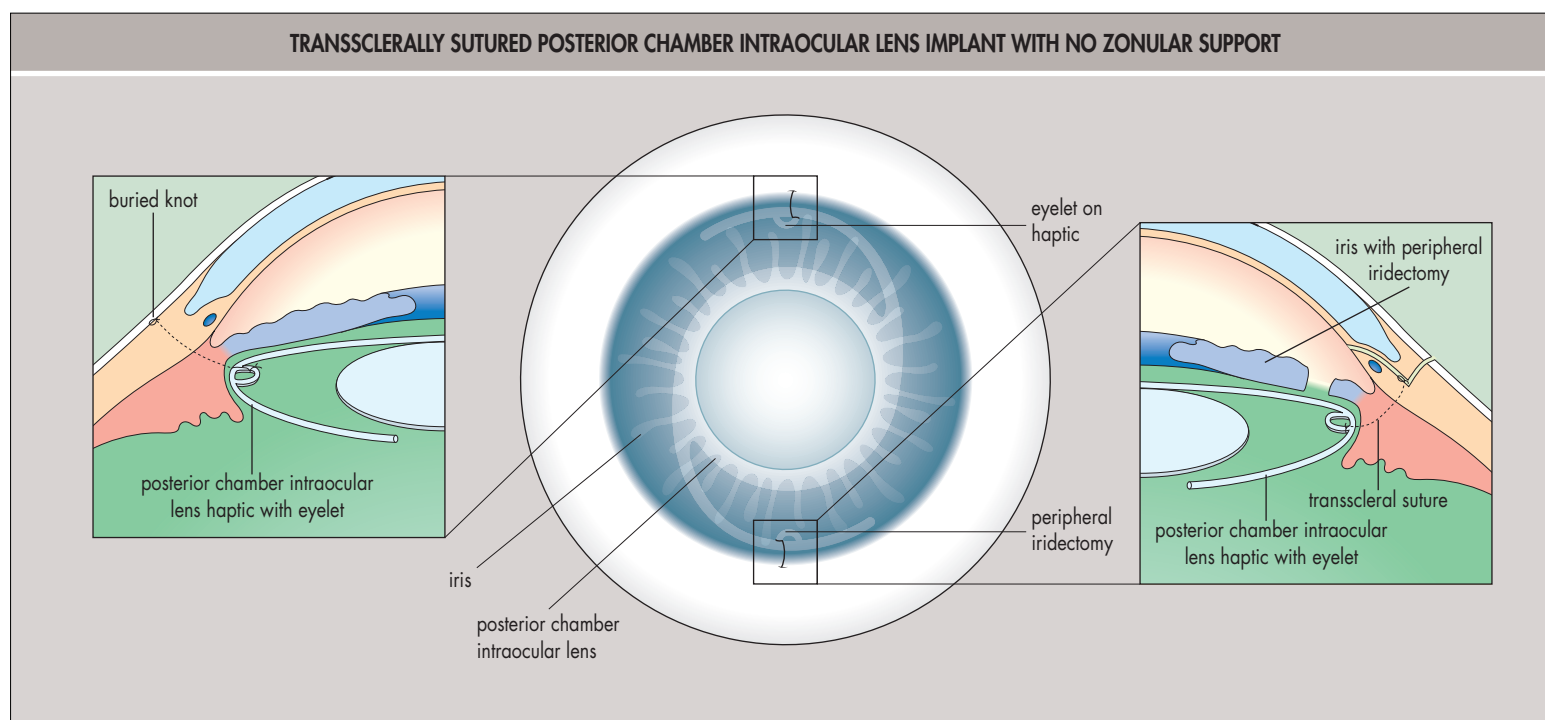

When necessary, posterior synechiolysis may be performed with use of a cyclodialysis spatula or viscodissection. The pupil may need to be enlarged if dilation is inadequate. The surgeon has the choice of manually stretching the pupil by using two instruments usually found on the surgical tray or by using an instrument specifically designed for pupillary dilation (e.g., the Beehler pupil dilator or the Malyugin ring). Pupillary membranes, if present, may need to be incised and stripped to further assist with dilation.

Acrylic lens implants are preferred and usually well tolerated by patients with uveitis.<sup>11</sup> Silicone lenses are discouraged in this setting because they may accumulate inflammatory precipitates postoperatively. In addition, it is best to avoid anterior chamber lenses, iris-sutured PCLs, and sulcus-supported PCLs, as they have a tendency to cause postoperative inflammation as a result of contact with the iris and the ciliary body. Whenever possible, a capsule-supported PCL is used. If capsular support is not present at the time of IOL implantation, a transsclerally fixated PCL may be placed, or the patient may be left aphakic.

In vitro and in vivo studies have demonstrated an advantage of heparin surface-modified polymethyl methacrylate (PMMA) lenses compared with regular PMMA lenses when looking at the adhesion of inflammatory

**Fig. 5.14.2 Sulcus Posterior-Chamber Intraocular Lens (PCL) Placement With Zonular Dehiscence.** The PCL is properly placed in the ciliary sulcus with the haptics oriented 90° away from the area of dehiscence. Placement in this orientation will decrease the likelihood that the haptics will prolapse posteriorly through the area of dehiscence and into the vitreous cavity.

**Fig. 5.14.3 Transscleral Sutured Posterior-Chamber Intraocular Lens (PCL) With No Zonular Support.** When no capsular or zonular support is present, a PCL may be secured by using two transscleral polypropylene or Gore-Tex sutures passed through eyelets on the haptics. The knots are rotated into the sclera to decrease the risk of long-term complications from knot erosion through the conjunctiva.

cells.<sup>12</sup> For this reason, heparin surface-modified PMMA lenses probably have an advantage over regular PMMA lenses in patients with history of uveitis. However, because of the necessity for a larger incision when using PMMA lenses, it remains unclear whether heparin surface-modified lenses have an advantage over foldable silicone or acrylic IOLs when otherwise small-incision phaco may be performed.

## COMPROMISED ENDOTHELIUM

Some patients, such as those with Fuchs' endothelial dystrophy, have a compromised corneal endothelium at the time of cataract surgery. The trauma of intraocular surgery causes further endothelial cell loss, potentially resulting in prolonged, and even irreversible, corneal edema. Pachymetry and specular microscopy may be performed as part of the preoperative

assessment on any patients with suspected endothelial dysfunction. Pre-operative risk factors for corneal decompensation in the setting of Fuchs' dystrophy include endothelial cell density less than 1000/mm<sup>2</sup>, central corneal thickness greater than 640 μm, and the presence of corneal epithelial edema.<sup>13</sup>

The surgeon should strive to minimize damage to the corneal endothelial cells during surgery. Rather than making the incision through temporal clear cornea, a more posterior, scleral tunnel approach may reduce endothelial disruption. A dispersive OVD will be more protective to the corneal endothelium than a cohesive OVD. The surgeon may wish to periodically refill the anterior chamber with OVD throughout the procedure. Phaco energy and time should be kept to a minimum, thus a chopping nucleofractis technique is preferred. Nuclear fragments should be emulsified as posteriorly as possible with the tip of the phaco hand piece directed away

from the cornea. FLACS is advantageous in these cases because it requires less phaco energy and causes less postoperative reduction in endothelial cell density.<sup>14</sup> Despite all these measures taken, however, corneal decompensation may still occur. Patients with corneal edema may benefit from topical hyperosmotic agents or corneal transplantation postoperatively. It is critical that adequate informed consent (including a discussion of the possibility of post-cataract surgery corneal transplantation) is obtained prior to the procedure. A myopic refractive target is advised if it seems likely that subsequent endothelial keratoplasty (EK) will be required, to counter the usual hyperopic refractive shift that accompanies EK procedures.

# Pediatric Cataract Surgery

Michael O'Keefe, Caitriona Kirwan, Elie Dahan<sup>†</sup>

# 5.15

**Definition:** Cataracts occurring in the pediatric age group, arbitrarily defined as birth to adolescence.

## Key Features

- Two main approaches are used to remove cataracts in children: pars plana and corneolimbic approach.
- Intraocular lenses, contact lenses, and spectacles are the most readily available means to correct aphakia in children.
- Advances in contact lens technology results in improved visual outcomes.
- Use of intraoperative triamcinolone and better surgical techniques reduces inflammation.
- Postoperative glaucoma remains a major problem.

## INTRODUCTION

Cataracts in childhood not only reduce vision but also interfere with normal visual development.<sup>1-3</sup> The management of pediatric cataracts is far more complex than the management of cataracts in adults. The timing of surgery, the surgical technique, the choice of the aphakia correction, and amblyopia management are of utmost importance in achieving good, long-lasting results in children.<sup>4-10</sup> Children's eyes are not only smaller than adults' eyes, but their tissues are much more reactive as well. The inflammatory response to surgical insult seems more pronounced in children, often because of iatrogenic damage to the iris. During the past 2 decades, the refinements that have occurred in adult cataract surgery have contributed to the further development of pediatric cataract surgery (PCS).<sup>2,4-8</sup> Certain adaptations and modifications in surgical technique are required to achieve results similar to those achieved in adults.<sup>2-8</sup> Furthermore, postoperative amblyopia management forms an integral part of visual rehabilitation in children.<sup>1-10</sup>

## HISTORICAL REVIEW

Discission of soft cataracts was first described by Aurelius Cornelius Celsus, a Roman physician who lived 2000 years ago. Discission remained the method of choice until the middle of the twentieth century. The technique consisted of lacerating the anterior capsule and exposing the lens material to aqueous humor for resorption and/or secondary washout. Repeated discissions often were required to manage the inevitable secondary cataracts.<sup>2</sup> Many early complications (e.g., plastic iritis, glaucoma, and retinal detachments) were associated with these early techniques.<sup>2,11</sup> With the advent of vitrectomy machines and viscoelastic substances, as well as the refinements in cataract surgery, these complications have been reduced markedly over the past 2 decades.<sup>2</sup>

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

A careful history assists the clinician in selecting the investigations needed for determining the cataract's etiology.<sup>2</sup> Information on problems during pregnancy (e.g., infections, rashes or febrile illnesses, exposures to drugs, toxins, or ionizing radiation) should be elicited. Family history of cataracts

### BOX 5.15.1 Laboratory Tests for Bilateral Nonhereditary Pediatric Cataracts

Complete blood count  
Random blood sugar  
Plasma calcium and phosphorus  
Urine assay for reducing substances after milk feeding  
Red blood cell transferase and galactokinase levels  
If Lowe's syndrome is suspected, screening for amino acids in urine  
Toxoplasmosis titer  
Rubella titer  
Cytomegalovirus titer  
Herpes simplex titer

in childhood or other ocular abnormalities can be relevant. Both parents and all siblings should be examined with a slit lamp to determine any lens abnormalities. When family history is positive, consultation with a geneticist is recommended. A thorough examination by a pediatrician to assess the child's general health and to elicit information about other congenital abnormalities may be helpful.

Laboratory tests in children who have bilateral cataracts in nonhereditary cases are listed in Box 5.15.1. Most unilateral pediatric cataracts are idiopathic and do not warrant exhaustive laboratory tests.

The ophthalmological part of the evaluation starts with a complete ocular examination, which includes an assessment of visual acuity, pupillary response, and ocular motility. Biomicroscopy follows and might necessitate sedation or even general anesthesia in very young patients. Indirect fundus examination with dilated pupils is made unless the cataract is complete. A- and B-scan ultrasonography is carried out in both eyes to compare axial lengths and to discover any posterior segment abnormalities.

## ALTERNATIVES TO SURGERY

The development of metabolic cataracts, such as those found in galactosemia, can be reversed if they are discovered in the early phases. With the elimination of galactose from the diet, the early changes in the lens, which resemble an oil droplet in the center of the lens, can be reversed.<sup>12</sup> Later on, lamellar or total cataracts develop and require surgery.

When lens opacities are confined to the center of the anterior capsule or the anterior cortex, dilatation of the pupils with cyclopentolate 1% twice daily can improve vision and postpone the need for surgery. Photophobia and partial loss of accommodation are side effects of this measure.

## ANESTHESIA

General anesthesia is presently the only anesthetic option in PCS. It is extremely important to request deep anesthesia throughout the procedure to minimize iatrogenic damage to iris and cornea.<sup>5,7,8</sup> Children's sclera is particularly elastic; therefore, any tension on the extraocular muscles results in loss of anterior chamber depth and increased intraocular pressure (IOP). A useful marker for anesthesia depth is the position of the eye during surgery. If the cornea moves upward or downward, the anesthesia is too light and should be deepened. When this guidance is followed, surgery is easier to perform.

## GENERAL TECHNIQUES

Unlike in adults, pediatric cataracts are soft. Their lens material can be aspirated through incisions that are 1–1.5 mm long at the limbus or can

<sup>†</sup>Deceased

be subjected to lensectomy through the pars plana. When intraocular lens (IOL) implantation is intended, a larger limbal wound is needed to introduce the IOL. With the use of foldable implants, the incision is not more than 3 mm. A scleral tunnel is better than a clear corneal incision (CCI). Unlike in adults, the wound should be securely sutured with 10.0 vicryl sutures to prevent wound dehiscence with iris incarceration—a common complication in children.<sup>2,4,5,7,8,10</sup>

## SPECIFIC TECHNIQUES

Two main approaches exist for the removal of cataracts in children: the pars plana approach and the corneolimbal approach.

Both techniques have advantages and disadvantages. The pars plana approach was developed with the advent of vitrectomy machines in the late 1970s.<sup>13,14</sup> It was intended to deal mainly with very young infants in whom surgery is more difficult. With the continuing refinements in cataract and implant surgery in adults, the pars plana approach gradually is being abandoned in favor of the limbal approach because the latter allows better preservation of the capsular bag for lens-in-the-bag IOL placement.<sup>2,5,7,8</sup>

### Pars Plana Approach

The pars plana approach is indicated mainly for neonates and infants under 2 years of age, particularly for those who have bilateral congenital cataracts, in which case immediate IOL implantation is not intended.<sup>2</sup> The technique requires a guillotine-type vitrectomy and balanced salt solution (BSS) containing epinephrine (adrenaline) 1:500 000. The location of the pars plana in infants can be 1.5–3.5 mm from the limbus. In the last decade, surgeons have largely abandoned the 20-gauge vitrectomy apparatus in favor of the 23-gauge or the 25-gauge version. A lensectomy–anterior vitrectomy is completed, sparing a 2- to 3-mm peripheral rim of anterior and posterior capsules. These capsule remnants are used to create a shelf to support a posterior chamber IOL that may be implanted later on in life.<sup>15</sup> It is important to avoid vitreous incarceration in the wounds by turning off the infusion before withdrawing the vitrectomy cutter from the eye. This precaution reduces the chances of suffering retinal traction and detachment later in life.<sup>16</sup>

This technique is rapid and allows for a permanently clear visual axis. The postoperative course is normally less complicated than that after the limbal approach because fewer maneuvers occur in the anterior chamber. Consequently, the iris and the corneal endothelium suffer less iatrogenic damage. In cases of children with bilateral cataracts, where an anesthetic risk exists because of unstable medical status, both eyes can be operated on sequentially at the same surgery, but treating both eyes as separate operations. This is now a procedure practiced by some pediatric ophthalmologists even when there is no anesthesia-related risk. This has the additional advantage of reducing the risk of relative amblyopia and freeing up operating room time, thus reducing trauma to the child.<sup>17</sup>

### Corneolimbal Approach

The corneolimbal approach is the most widely used surgical technique. A long tunnel limbal incision reduces the risk of iris prolapse. Sometimes, the pupil is meiotic and will not dilate well. This requires intracameral phenylephrine 2.5% and/or iris hooks. Viscoelastic materials are necessary to maintain the anterior chamber depth. Some use an anterior chamber maintainer (ACM) to maintain the chamber, and it can provide a steady intraoperative IOP and helps keep the pupil dilated throughout the procedure because of positive hydrostatic pressure.

Two limbal incisions are made with a 23-g micro-vitreo-retinal blade (MVR; Alcon Laboratories Inc., Fort Worth, TX). These allow for use of a bimanual technique with one cannula infusing fluid to the anterior chamber and the opposite one aspirating the lens material.

Various techniques have been described to open the anterior capsule. The younger the child, the more difficult it is to perform a capsulorrhexis. Infants have a very elastic anterior capsule that easily tears toward the periphery. A manual capsulorrhexis using a push/pull technique has been described.<sup>18</sup> A more practical alternative is to use a vitrectomy probe to create a small central opening in the anterior capsule (Fig. 5.15.1). This hole can be enlarged gradually by biting into the anterior capsule with the vitrector until the desired 4- to 5-mm opening is achieved. Another alternative is the Oertli diathermy system, which has the effect of creating a controlled central 5-mm round capsulotomy<sup>19</sup> (Fig. 5.15.2). Gentle hydrodissection and hydrodelineation free the lens material, which can be aspirated by using the bimanual technique or with the vitrector. The

**Fig. 5.15.1**  
Anterior Capsulotomy Performed With Use of a Vitrectomy Probe in a Case of Congenital Cataract. Note the use of the anterior chamber maintainer for a deep anterior chamber and a well-dilated pupil.

**Fig. 5.15.2** Oertli diathermy system for performing capsulotomy.

**Fig. 5.15.3**  
**Elective Posterior Capsulectomy and Deep Anterior Vitrectomy.** This is performed with the use of a vitrectomy probe, after all the lens material has been aspirated within the capsular bag.

management of the posterior capsular bag is determined by the age of the patient and as to whether an implant should be inserted. Most surgeons agree that infants under 6 years of age should receive an elective posterior capsulectomy and anterior vitrectomy.<sup>20</sup> Posterior capsulorrhexis is performed manually or with a vitrector.

Its diameter should be at least 4 mm (Fig. 5.15.3). The anterior vitrectomy should be generous, removing one third of the vitreous to ensure a permanently clear visual axis. Smaller posterior capsulectomies and shallow anterior vitrectomies close, especially in neonates. Posterior capsulectomies, either alone or combined with shallow anterior vitrectomy, does not guarantee a permanent clear visual axis because lens epithelial cells regrow and can form new membranes.

A modification of the technique includes a translimbal capsulorrhexis and lens aspiration, then insertion of the IOL into the capsular bag. The wound is closed, and the anterior chamber is maintained with either viscoelastic or ACM. The surgeon then goes through the pars plana to perform a posterior capsulorrhexis and anterior vitrectomy by using a vitrector. Leaving the posterior capsule intact, especially in neonates and children under 2 years of age, results in very early posterior capsule opacification. The use of yttrium–aluminum–garnet (YAG), either immediately after surgery or later, has had limited success. Because of logistics, it is not possible unless the surgeon has access to a horizontal laser system.

## CHOICES FOR CORRECTION OF APHAKIA IN CHILDREN

Spectacles, contact lenses, and IOLs are the most readily available means to correct aphakia in children.

### Spectacles

Aphakic spectacles provide satisfactory correction only in cases of bilateral aphakia in which anisometropia does not represent a problem.<sup>2</sup> Most of the patients develop good visual acuity with the use of spectacles, provided that the eyes are not excessively microphthalmic.<sup>2</sup> The disadvantages of spectacles are cosmetic concerns and the poor optical quality of high-plus lenses.

### Contact Lenses

During the 1970s and 1980s, contact lenses were described as the method of choice to correct unilateral and bilateral aphakia in childhood.<sup>2,9,10</sup> Contact lenses provide better optical correction compared with spectacles, and their dioptric power can be adjusted throughout life. However,

## BOX 5.15.2 Guidelines for the Choice of Intraocular Lens Dioptic Power

### Children Less Than 2 Years Old

- Do biometry, and undercorrect by 20%, or
- Use axial length measurements only
- Axial length, IOL dioptric power
  - 17 mm, 25 D
  - 18 mm, 24 D
  - 19 mm, 23 D
  - 20 mm, 21 D
  - 21 mm, 19 D

### Children Between 2 and 8 Years Old

- Do biometry, and undercorrect by 10%

the management of contact lenses in children can be very difficult and costly because of frequent loss of lenses, recurrent infections, and poor follow-up. The Infant Aphakia Treatment Study (IATS)<sup>21</sup> was a multicenter randomized clinical trial comparing cataract surgery with or without IOL implantation in infants ages 1–6 months with clinical congenital cataracts. The IATS authors concluded that there was no significant difference in the median visual acuity between eyes that underwent primary IOL implantation and those left aphakic. However, significantly more adverse events occurred, and a need existed for additional intraoperative procedures in the IOL group. Those authors concluded that primary IOLs should be reserved for those cases where, in the opinion of the surgeon, the use of handling of a contact lens would result in significant periods of uncorrected aphakia. During the last 2 decades, many technical problems have been overcome. One such recent advance is the introduction of extended wear silicone elastomer and custom rigid gas permeable contact lenses that are a great advance.<sup>22</sup> Some problems, such as cost of replacement and need for frequent replacement because of changes in refractive error and lens loss, have persisted.

## Intraocular Lenses

The IOL option was originally advocated in cases of unilateral pediatric cataracts because it facilitates amblyopia management by providing more permanent correction.<sup>2,4,5,7,8,10,13</sup> Implanting an IOL in a growing eye is not an ideal solution. The aim in the IOL option, unlike in the contact lens alternative, is to correct most, but not all, of the aphakia; the residual refractive error has to be corrected with the use of spectacles, which can be adjusted throughout life.

The implantation of anterior chamber angle supported IOLs in children was discontinued in the mid-1980s. Devastating complications, such as secondary glaucoma and corneal decompensation, were attributed to these IOLs, especially in younger patients. Posterior chamber intraocular lens (PCL) implantation represents, by far, the best method for the correction of aphakia.

### Selection of Intraocular Lenses

The choice of the dioptric power of IOL for young children is the main difficulty faced by the ophthalmologist.<sup>2</sup> Pediatric IOLs are not yet readily available,<sup>23,24</sup> and the rapid growth of the eye during the first 2 years of life makes an effective choice difficult.<sup>2,4,7,8,25–27</sup> (Box 5.15.2). Nevertheless, in the 1990s, increasingly positive reports were published on the use of PCLs in children and even in neonates.

The material from which the IOL is made must have a long track record of safety. Polymethyl methacrylate (PMMA) IOLs have been in use for more than 50 years; PMMA is probably the safest material to be used in children until similar follow-up data on other biomaterials become available. Nevertheless, during the last decade, many surgeons have switched to the use of foldable hydrophobic IOLs in children. The actual size of the capsular bag and the ciliary sulcus in children has been ascertained by the work of Bluestein et al.<sup>24</sup> PCLs, which were originally oversized, have been reduced from 13–14 mm to 12–12.5 mm in diameter in most modern models. In children, it is even more important to implant an IOL of the correct size.<sup>24</sup> Pediatric IOLs should not exceed 12 mm in overall diameter, considering that the average adult ciliary sulcus diameter rarely exceeds 11.5 mm. Ideally, the pediatric IOL should be available in diameters of the range 10.5–12 mm.<sup>24</sup> The choice of IOL size is determined mainly by the site of implantation (i.e., lens-in-the-bag or ciliary sulcus).

**Fig. 5.15.4** Schematic drawing of the lens-in-the-bag implantation (A) and the bag-in-the-lens implantation (B).

Both the biometry and the age of the child determine the choice of the IOL dioptric power. Two main age groups exist with regard to PCS: patients younger than 2 years and patients between 2 and 8 years of age. In the first group, the axial length and the keratometric (K) readings change rapidly, whereas in the second group the changes are slower and more moderate.<sup>25–27</sup> To counteract the large myopic shift that occurs, it is advisable to undercorrect in children with IOLs so that they can grow into emmetropia or mild myopia in adult life.<sup>25–27</sup>

Those who are under 2 years of age should receive 80% of the power needed for emmetropia at the time of surgery. Because the K readings also change rapidly during the first 18 months of life, it is practical to rely on the axial length only when the IOL dioptric power is chosen for infants (Box 5.15.2). The postoperative residual refractive error is corrected by spectacles, which can be adjusted as will as the child grows. Infants and toddlers can tolerate up to 6 D of anisometropia, which disappears within 2–3 years.<sup>27</sup> Most of the infants who have unilateral pseudophakia need a patch over the sound eye for half their waking hours for the first year and for 80% to 90% of the waking day until age 4 or 5 years. Patches alleviate the symptoms of anisometropia but at the same time affect the chances of development of good binocularity.<sup>26</sup>

For the age range of 2–8 years, the IOL dioptric power should be 90% of that needed for emmetropia at the time of surgery (see Box 5.15.2). The induced anisometropia is moderate and lessens with the expected myopic shift that occurs in adolescence.<sup>25–27</sup>

### Implantation in Children Under 2 Years of Age

Intraocular implantation is controversial in infants. However, implantation in those beyond 6 months and beyond 1 year of age is widely practiced, particularly in unilateral cases. The most popular approach involves cataract aspiration and capsulectomy through the corneal sclera wound. The implant is inserted through the corneal sclera wound into the capsular bag. Elective posterior capsulectomy and anterior vitrectomy are performed through the pars plana. The results of the IATS and improved contact lens technology may see a shift away from IOL in the age group.<sup>21</sup>

### Implantation in Children Above 2 Years of Age

For children older than 2 years, the IOL should be inserted because the eye has reached nearly the adult size, although its sclera is much softer. Gimbel<sup>28</sup> has described a special IOL implantation technique for this group of patients. This technique requires extreme dexterity because both anterior and posterior capsulorhexes are performed. The IOL haptics are placed in the bag fornices, while the optic is protruded through both capsulorhexes to be captured beneath the posterior capsule remnants. Tassignon recently developed a new technique for a special IOL called *bag-in-the-lens*.<sup>29</sup> The technique consists of creating an anterior and posterior capsulorhexes. The specially designed IOL has, at its periphery, a groove that contains both anterior and posterior capsule rims (Fig. 5.15.4). Although technically demanding, promising early results indicate that this technique may eliminate the need for elective anterior vitrectomy.

### Postoperative Treatment

The eyes of infants and younger children are highly reactive to surgery. These eyes produce excessive fibrin, and as a result, an intense inflammatory response occurs soon after surgery. The pupil remains meiotic, and

corneal edema occurs. The inflammation is worse if the surgery has been traumatic. A combination of intense topical and systemic corticosteroids is used for the first few weeks with use of atropine or cyclopentolate to dilate the pupil. The medications are tapered over about 4–6 weeks. The use of triamcinolone 4 mg in 0.1 mL has significantly reduced the inflammation and lessened the need for intense topical and systemic corticosteroids.<sup>30</sup>

## COMPLICATIONS

Intraoperative complications are related to the age of the child at surgery, anesthesia, and surgical technique. The anterior chamber tends to collapse, the iris can protrude through the wound, and the pupil constricts. Deep anesthesia, good surgical technique, ACM, iris hooks, and proper vitrectomy help minimize these problems.

### Postoperative Complications

Early complications include fibrinous uveitis, high IOP, incarceration of iris in the wound, and endophthalmitis. Late complications include dislocation of the IOL, chronic iritis, glaucoma, and retinal detachment. The rate of glaucoma or suspected glaucoma in the IATS 1 year after surgery was 12% at 1 year and 30% at 5 years follow-up, with no difference between eyes that were aphakic and those that were pseudophakic.<sup>21</sup> Many reasons have been reported as a cause of glaucoma; delaying surgery until the infant is 6 weeks old is thought to reduce the risk.<sup>31,32</sup>

### Amblyopia Management

The child's parents must understand that surgery is only the start of visual rehabilitation and that rehabilitation must continue throughout childhood.

Unilateral cases are the most difficult to manage.<sup>2,4,5,7–10</sup> Amblyopia treatment starts soon after surgery, after postoperative inflammation subsides and the medium becomes clear. The initial treatment must be aggressive to boost vision in the deprived eye. Occlusion of the sound eye is carried out for half the waking day for the first year. Therefore, occlusion should be maintained 80% to 90% of the waking day. Soon after surgery for bilateral aphakia, spectacles are prescribed, a bifocal lens of +3 should be prescribed at 2 years. For unilateral aphakia and pseudophakia, patching should be continued until the child is 4–5 years of age. The patch wear time can be reduced gradually but should not be abandoned until the child reaches 8–9 years of age.

### Options to Correct Myopic Shift

The growth of aphakic and pseudophakic eyes is unpredictable. This particularly applies to pseudophakic eyes.<sup>33</sup> A myopic shift of 7 D or more is not uncommon. IOL exchange when an implant has been in place for more than a year is extremely difficult and carries significant risks. However, contact lenses,<sup>22</sup> refractive surgery,<sup>34</sup> and secondary IOLs to correct the myopia are now the preferred options. Both the techniques and the outcome of these various options have produced good visual outcomes with low risk of complications.

## OUTCOME

The visual outcome depends largely on the type of cataract, the laterality of the pathology, the timing of intervention, the quality of surgery, and, above all, the management of amblyopia. It is possible to achieve nearly normal vision even in cases of unilateral congenital cataracts, provided the amblyopia management is aggressive.<sup>2–10,24</sup> Binocularity usually is poor in these cases, but some gross stereopsis can be expected.<sup>35</sup> Children with aphakia and pseudophakia certainly should be followed up throughout their childhood and preferably throughout life.<sup>36</sup>

# Complications of Cataract Surgery

Thomas Kohnen, Li Wang, Neil J. Friedman, Douglas D. Koch

# 5.16

**Definition:** All unwanted events during or after conventional cataract surgery with potential threat to the normal structure and/or function of the eye.

## Key Features

- Intraoperative complications, depending on incision, perforation, detachment of structures, burns, anterior capsule, posterior capsule, zonulae, capsulorhexis, iris problems, subluxation, sulcus structure, hemorrhage.
- Postoperative complications, depending on wound characteristics, epithelial characteristics, corneal irregularities and problems, intraocular hemorrhage, glaucoma, problems with architecture of the implanted intraocular lens, problems with the retina, dislocation of the lens.

## Associated Feature

- Understanding the mechanism of several complications in cataract surgery and performing the correct steps to minimize further unwanted negative results.

## INTRODUCTION

Phacoemulsification (“phaco”), sutureless, self-sealing tunnel incisions, and foldable intraocular lenses (IOLs) have changed cataract surgery dramatically over the past 2 decades. Postoperative astigmatism and inflammation are typically minimal; visual recovery and patients’ rehabilitation are accelerated. The published literature indicates that modern cataract surgery, although certainly not free of complications, is a remarkably safe procedure, regardless of which extraction technique is used.<sup>1</sup>

Using rigid criteria for scientific validity, Powe et al.<sup>1</sup> analyzed 90 studies published between 1979 and 1991, addressing visual acuity ( $n = 17\,390$  eyes) or complications ( $n = 68\,316$  eyes) following standard nuclear expression cataract extraction with posterior chamber IOL implantation, phaco with posterior chamber IOL implantation, or intracapsular cataract extraction with anterior chamber IOL implantation. Strikingly, the percentage of eyes with postoperative visual acuity of 20/40 or better was 89.7% for all eyes and 95.5% for eyes with no pre-existing ocular comorbidity. The incidence of sight-threatening complications was less than 2%.

In this chapter, the key elements in the prevention, recognition, and management of the major intraoperative and postoperative complications of cataract surgery are discussed.

## INTRAOPERATIVE COMPLICATIONS

### Cataract Incision

The cataract incision serves as more than just the port of access to the anterior segment; it is a critical step of the operation that affects ocular integrity and corneal stability. The traditional limbal or posterior limbal incision has been largely replaced by tunnel constructions, which can be located in the sclera, limbus, or cornea and are characterized by their

greater radial length and an anterior entry into the anterior chamber to create the self-sealing internal corneal valve. Advantages of tunnel incisions are increased intraoperative safety, decreased postoperative inflammation and pain, increased postoperative watertightness, and reduced surgically induced astigmatism.<sup>2</sup>

### Tunnel Perforation

Tearing of the roof of the tunnel predisposes to excessive intraoperative leakage, which compromises anterior chamber stability, and to postoperative wound leakage. If the tear occurs at either edge of the roof, surgery usually can be completed using the initial incision, proceeding slowly and observing the wound carefully as instruments are introduced or manipulated in the eye. It usually is preferable to suture the incision at the conclusion of surgery, even if the wound is watertight, to restore a more normal architecture and prevent external wound gape.

If, however, the roof is perforated in the center of the flap, and this is noted before the anterior chamber is entered, creation of a new incision should be considered. If the cut is extremely small (e.g.,  $< 0.5$  mm), sometimes the same procedure as for lateral roof tears (see above) can be used. Before IOL insertion, the opposite margin of the wound is enlarged, and to prevent further tearing, the incision is made larger than normal for IOL insertion. Suture closure usually is advisable to restore normal wound architecture.

If the floor of the tunnel is perforated, which can happen during scleral tunnel dissection, surgery usually can be performed through this wound; care must be taken to avoid trauma to any prolapsing uveal tissue. The perforation should be closed with sutures or fibrin glue.

### Descemet’s Detachment

Detachment of Descemet’s membrane can be a major postoperative complication, resulting in persistent corneal edema and decreased visual acuity. To prevent Descemet’s detachment, the surgeon should carefully observe the inner lip at each phase of the procedure. To avoid blunt stripping of Descemet’s membrane during enlargement of the wound, a sharp metal or diamond blade is recommended.

If detachment is caused by viscoelastic injection, the agent must be removed by using a blunt cannula. Intraoperatively, repositioning of Descemet’s membrane usually can be achieved by injecting balanced salt solution (BSS) or occasionally air or an ophthalmic viscosurgical device (OVD) through the paracentesis site. With the experience we have gained over the last 5 years with Descemet’s membrane endothelial keratoplasty (DMEK) air or gas injection (20% sulfahexafluoride [ $\text{SF}_6$ ]) can perfectly reattach a stripped Descemet’s membrane.

If a visually significant Descemet’s detachment is present postoperatively, the authors of this chapter prefer to intervene after 2–3 weeks; however, late spontaneous reattachment 2–3 months (in one case, 10 months) postoperatively has been reported.<sup>3,4</sup> To reattach Descemet’s membrane, the patient is positioned at the slit lamp after several drops of anesthetic agent and antibiotics have been administered. A paracentesis incision is made inferotemporally. A 27- or 30-gauge cannula is attached to a syringe with a filter, and the syringe is filled with  $0.5\text{--}1\text{ cm}^3$  of air or, for eyes that have an unsuccessful injection of air alone, an expansive gas (e.g.,  $\text{SF}_6$ ). Using the cannula, approximately 50% of the aqueous is drained, and the chamber is reformed with injection of the gas. Another technique

**Fig. 5.16.1 Corneal Burn Following Phacoemulsification (Phaco).** In this patient with an apparent filtering bleb, phaco was performed through a temporal, clear corneal incision (CCI). Posterior capsular rupture was suspected; the surgeon injected a highly retentive ophthalmic viscosurgical device beneath and in front of the nucleus to minimize the risk of posterior dislocation of the nucleus. Phaco was instituted with low flow and vacuum settings, and a severe corneal burn was immediately produced because of obstruction of the phaco tip by the viscoelastic material. The incision was closed with several interrupted sutures. Many of these pulled through the injured tissue, and as a result, additional suturing was required several days later. Postoperatively, the patient has 5 D of surgically induced astigmatism that has persisted for more than 5 years.

for repairing Descemet's detachments using intracameral gas injection at the slit lamp microscope has been reported.<sup>5</sup> A 25-gauge needle on a 3-mL syringe filled with the gas and another 25-gauge needle are advanced through the corneoscleral limbus at opposite clock hours with the bevel up and the needles oriented parallel to the iris plane. The plunger on the syringe is depressed to inject the gas and fill the anterior chamber while aqueous humor is allowed to egress from the opposing 25-gauge needle. More complicated cases may require direct suturing.<sup>6</sup>

## Thermal Burns

Part of the energy produced by the phaco tip is dissipated as heat. This heat is conducted into the eye along the titanium tip and then cooled by the ongoing flow of the irrigation-aspiration fluid. If for any reason the flow is blocked, a corneal burn can occur within 1–3 seconds. The most common cause is inadequate flow through the phaco tip because it has been obstructed by a retentive OVD; this problem arises from use of low flow and vacuum settings. The critical warning sign is the appearance of milky fluid that is produced around the tip as emulsification commences.

To avoid corneal burns, phaco and irrigation-aspiration functions should always be tested before the eye is entered. Some of the viscoelastic material that overlies the nucleus can be aspirated before the start of emulsification to ensure that aspiration is adequate. To prevent constriction of the irrigating sleeve, an incision size that is appropriate for each particular phaco tip should be selected. If a burn does occur, meticulous suturing of the wound with multiple radial sutures (Fig. 5.16.1) is required. A bandage contact lens may assist with wound closure. Severe postoperative astigmatism can result. The smaller incision size and new-generation phaco tips continue to contribute to a reduction in the incidence of corneal burns.

## Anterior Capsulectomy

### Preventing Radial Tears in the Anterior Capsule

For phaco, the preferred method of anterior capsulectomy is capsulorrhexis. It is now recognized that radial tears in the anterior capsule can pose significant risks because of their tendency to tear into the equatorial region of the lens<sup>7</sup> and extend into the posterior capsule. This causes posterior capsular rupture, loss of lens material, and IOL decentration. The surgeon's goal, therefore, must be to retain an intact capsulorrhexis. A common cause of radial tears is irretrievable loss of the capsulorrhexis tear peripherally beneath the iris. To prevent this, the following steps should be considered:

- The anterior chamber should be reinflated with an OVD.
- The vector forces of the tear should be changed to redirect the tear in a more central direction.
- If the tear is lost beneath the iris, the capsulorrhexis should be restarted from its origin, proceeding in the opposite direction (if possible, this

new capsulorrhexis should end with the incorporation of the original tear in an outside-in direction; however, the original tear is often too peripheral to permit this, and a single radial tear is created).

An alternative approach to a “lost” capsulorrhexis is to convert to a “can opener” capsulectomy. It may, indeed, be safer to have multiple tears, rather than a single one, because forces that extend these tears can be distributed to multiple sites, which reduces the likelihood of a tear extending equatorially.

### Excessively Small Capsulorrhexis

If the diameter of the capsulorrhexis opening is excessively small, the tear should be directed more peripherally and continued beyond the original point of origin before completion of the capsulorrhexis; this procedure removes an annulus of capsule and enlarges the opening. If the capsulorrhexis has been terminated and the opening is too small, a new tear can be started by making an oblique cut with Vannas scissors or a sharp needle. It usually is preferable to enlarge the capsulorrhexis after IOL implantation, to minimize the risk of radial tears during lens implantation.

### Minimizing Complications When Radial Tears Are Present

If radial tears are present, several modifications in surgical technique should be considered to minimize the risk of tear extension into the posterior capsule:

- Hydrodissection or hydrodelineation is performed gently to minimize distention of the capsular bag.
- Cracks during emulsification are made gently away from the area(s) with radial tears. Alternatively, as much of the nucleus as possible is sculpted within the capsular bag, and the rest is removed at the iris plane. The height of the infusion bottle is kept low to prevent overinflation of the anterior chamber (which can cause the tear to extend peripherally).
- The IOL should be placed with the haptics 90° away from the tear. One-piece polymethyl methacrylate (PMMA) lenses tend to maintain better centration in these situations. Rotation of the IOL should be minimized. The OVD should be removed in small aliquots while gentle infusion of BSS is performed through a side-port incision.
- It is important to avoid anterior chamber collapse at any phase of the operation when radial tears are present. Anterior bulging of the posterior capsule can place increased stress on a radial tear, which predisposes its extension into the equator and posterior capsule. To avoid this, the chamber is deepened each time the phaco or irrigation-aspiration tip is removed from the eye; this is done by injecting fluid, OVD, or perhaps air through the paracentesis incision with a syringe while the instrument is removed from the incision.

## Nucleus Expression Cataract Extraction

Complications related to nucleus expression are covered in Chapters 5.11 and 5.12.

## Complications During Phaco

### Hydrodissection

Hydrodissection was developed to permit easy rotation of the nucleus in the capsular bag and to facilitate removal of various layers of the lens by eliminating their adhesion to surrounding tissues. Two major complications of hydrodissection are inadequate hydrodissection and overinflation of the capsular bag. The former results in a nucleus that does not rotate, and this predisposes to zonular dehiscence if excessive force is exerted on the nucleus. This can be avoided by making an additional hydrodissection, particularly in quadrants that have not been hydrodissected before. U-shaped cannulas are useful to hydrodissect subincisional regions of the lens not accessible with straight or angulated cannulas.

Overinflation of the capsular bag can predispose to prolapse of the nucleus into the anterior chamber, which might compromise the ease or safety of nucleus emulsification. A serious complication of overinflation is posterior capsular rupture, with loss of the nucleus into the vitreous. This is more likely to occur in eyes with long axial lengths, (hyper)mature cataracts, or with fragile posterior capsules, such as those found in patients who have posterior polar cataracts.<sup>8</sup>

### Iris Prolapse or Damage

Iris prolapse is usually caused when the anterior chamber is entered too posteriorly, such as near the iris root. If this is noted early in the case

and interferes with the easy introduction of instruments into the eye, it is advisable to suture the incision and move to another location.

A second and more ominous cause of iris prolapse is an acute increase of intraocular pressure (IOP) accompanied by choroidal effusion or hemorrhage. In this instance, the surgeon should attempt to identify the cause and lower the IOP. Digital massage on the eye, pressing directly on the incision, may successfully lower the pressure. It is useful to examine the fundus to ascertain whether a choroidal effusion or hemorrhage exists. With choroidal effusion, aspiration of vitreous can be helpful, as can the administration of intravenous mannitol. If a choroidal hemorrhage occurs or if the increased IOP from an effusion is resistant to treatment, it usually is best to terminate the surgery. The wound is sutured carefully; intraocular miotics are administered, and a peripheral iridectomy may be performed to help reposition the iris. For effusions, surgery can be deferred until later in the day or the next day, when the fluid dynamics of the eye have returned to a more normal state. If a limited choroidal hemorrhage has occurred, it is best to wait 2–3 weeks before attempting further surgery.

Trauma to the iris from prolapse or emulsification with a phaco tip can produce an irregularly shaped pupil and iris atrophy and can predispose to posterior synechiae formation. If iris damage is produced inferiorly through contact with the phaco tip, loose strands of tissue should be cut to reduce the likelihood of these being aspirated into the phaco tip. Another option is to use a single iris hook to retract the inferior iris, holding it away from the phaco tip for the duration of the procedure.

### Floppy Iris Syndrome

This complication has been observed during phaco in patients receiving  $\alpha_1$ -antagonist agents, such as tamsulosin (Flomax). The symptoms include billowing and floppiness of the iris, prolapse of the iris to the main and side incisions, and progressive constriction to the pupil during surgery.<sup>9</sup>

When treating patients who receive  $\alpha_1$ -antagonist agents, the surgeon can try to avoid severe intra- and postoperative complications by preoperative use of atropine, intraoperative epinephrine (adrenaline), lower phaco vacuum and aspiration settings, the use of supercohesive OVDs, and various iris hooks and pupil dilators.<sup>10</sup>

### Trapped Nucleus

In this situation, the nucleus seems to be trapped within the capsular bag; it resists rotation, elevation, or both. This usually indicates a nucleus that requires further hydrodissection, which should be repeated in regions not previously hydrodissected (e.g., laterally and inferiorly with angled or straight cannulas, superiorly with U-shaped cannulas; if these cannulas are not available, additional paracentesis sites can be created in strategic locations).<sup>11</sup> If this fails to achieve adequate mobilization of the nucleus, viscodissection can be performed. An OVD is injected in the plane of the hydrodissection, which usually results in elevation of the nuclear remnant. When re-entering the eye with the phaco tip, irrigation should not be used until a second instrument has been inserted through the stab incision and placed below the nucleus; when irrigation and aspiration begin and the OVD is removed, the second instrument prevents the nuclear piece from falling back into the posterior chamber.

If the capsulorrhexis is small and the nuclear circumference is intact, nuclear elevation through the capsulorrhexis may not be possible. Additional sculpting might be required to thin the nucleus centrally or to remove some of the peripheral nucleus. After the nucleus has been sufficiently thinned, an instrument, such as a Sinskey hook or spatula, can be teased posteriorly through the remaining nuclear tissue. This enables elevation of a portion of the nucleus and thereby facilitates access to the remainder.

### Subluxated Lens

The surgical approach for subluxated lenses (Fig. 5.16.2) is determined by lens stability, lens position, and nuclear density.<sup>12</sup> In a subluxated lens with adequate zonular support, phaco (or nuclear expression) can be performed. OVD is injected as needed throughout the surgery to tamponade the vitreous in areas of zonular dehiscence. Extensive hydrodissection and viscodissection should be carried out. Depending on the density of the nucleus, either phaco in the capsular bag or anterior chamber phaco under a retentive viscoelastic is performed. Any form of zonular stress should be minimized, particularly with nuclear rotation. Although not the topic of this chapter, femtosecond laser-assisted capsulectomies can help in these situations because they produce minimal stress to the zonules.

If phacodonesis is present but the lens has not fallen posteriorly, a soft nucleus sometimes can be removed by phaco-aspiration, whereas a

**Fig. 5.16.2 Subluxated Lens.** This patient had a subluxated lens caused by ocular trauma. The crystalline lens was removed using a pars plana approach, and a sulcus-sutured intraocular lens was implanted.

hard nucleus should be extracted by using an intracapsular approach. Pars plana vitrectomy is an excellent option for these cases as well; it certainly is preferred when the lens is subluxated posteriorly.

The location of the IOL placement depends on the status of the capsular bag after cataract removal. If zonular disruption is minimal (fewer than 3 clock hours), the IOL can be implanted into the capsular bag with the haptic orientated in the meridian of the zonular defect. If the zonular disruption is larger, options include the following:

- Ciliary sulcus implantation, possibly with scleral or iris fixation of one or both haptics.
- Insertion of one haptic into the capsular bag and suturing of the second haptic into the sulcus.
- Endocapsular ring implantation to stabilize the capsular bag or a Cionni ring to suture the capsular bag/ring complex to the sclera.<sup>13–15</sup>
- Anterior chamber lens implantation (angle-supported or iris fixated).<sup>16</sup>
- An angle-supported anterior chamber lens, which is acceptable if no anterior chamber angle pathology, glaucoma, or uveitis is present.<sup>14</sup>
- Posterior chamber lens implantation (as iris fixated retropupillary Artisan type).<sup>17</sup>

### Ruptured Posterior Capsule

Posterior capsule rupture is the most common serious intraoperative complication of cataract surgery.<sup>18</sup> Proper management, however, can result in minimal morbidity to the patient. A posterior capsular rent is more likely to occur in eyes with small pupils, hard nuclei, or pseudo-exfoliation syndrome. Recent reports suggest that the visual prognosis of patients who have broken posterior capsules is excellent. The key factors are to minimize ocular trauma, meticulously clean prolapsed vitreous from the anterior segment, if present, and ensure secure fixation of the IOL.

### Before Nucleus Removal

A capsular break noted before nucleus extraction is a potential disaster. The first objective is to prevent the nucleus from being dislodged into the vitreous cavity. An OVD can be injected posterior and anterior to the nucleus to prevent its posterior displacement and to cushion the corneal endothelium. Another alternative is to insert an instrument through a pars plana incision 3 mm posterior to the limbus into the vitreous, which Kelman had described as “posterior assisted levitation” (Charles Kelman, personal communication). The nucleus is pushed gently anteriorly so that it can be captured in front of the iris and safely removed from the eye. Once the nucleus or its remnants have been repositioned in the anterior chamber, the choice is to convert or to continue the emulsification. The latter course can be more hazardous and predisposes to enlarging the rent and possibly losing the nucleus into the vitreous. In most circumstances, the nucleus should be managed by sufficiently enlarging the wound to facilitate easy extraction of the nucleus on a lens loop. However, in the case of a small break or when only a small amount of nucleus is left, it may be possible to cover the posterior capsular opening with a retentive OVD and complete the phaco. A Sheets glide can also be used as a “pseudo-posterior capsule” to facilitate completion of phaco.

Vitreous loss almost always accompanies posterior capsular rupture that occurs before nucleus removal. Whenever feasible, vitrectomy should be performed before the nuclear pieces are removed. Clearly, this should not be done if it makes loss of the nucleus into the vitreous more likely.

### During Cortical Irrigation–Aspiration

When capsular rupture occurs during aspiration of the cortex (which is, in fact, the most common cause),<sup>7,19</sup> a key factor is the status of the vitreous. If no vitreous is present in the anterior segment, vitreous loss often can be averted. An OVD can be injected through the capsular opening to push the vitreous posteriorly. Cortical removal can be completed using low-flow irrigation. Options include using a manual system; a dry approach, aspirating with a cannula in the chamber filled with OVD; a bimanual approach through two paracentesis openings; and automated irrigation–aspiration with all settings reduced.<sup>20</sup> The cortex should be stripped first in the region farthest from the rent, and the direction of stripping should be toward the rent. Because it can be hazardous to remove the cortex in the region of the rent, the cortex is sometimes better left in the eye, to avoid the possibility of enlarging the rent and precipitating vitreous loss. One option to prevent extension of the rent is to convert the tear into a small posterior capsulorrhexis, which eliminates any radially orientated tears that could extend with further surgical manipulation.

If vitreous is present in the anterior segment, vitrectomy should be performed first, with the necessary caution being taken to prevent extension of the rent. Depending on the type of capsular tear, the vitrectomy is performed through either the limbal incision or the pars plana. The former approach is used when the tear is located near the incision, which permits vitrectomy with minimal risk of enlargement of the tear. A pars plana approach is preferred when the tear is remote from the incision and, therefore, less accessible anteriorly. In either case, irrigation is provided with an infusion cannula in the paracentesis opening, or a 23-gauge trocar is inserted through the pars plana. After a thorough anterior vitrectomy, the remaining cortical material can be removed using one of the techniques described earlier or using the vitrector in the aspiration mode without cutting.

### Intraocular Lens Insertion

Careful inspection of the anatomy of the capsule and zonules is required to determine the appropriate site for IOL implantation. There are five choices: capsular bag; iris fixated (retropupillary or prepupillary); ciliary sulcus; sutured posterior chamber; and anterior chamber.

#### Capsular Bag

If the rent is small and relatively central, and if the anterior capsular margins are well defined, the posterior chamber IOL can be implanted into the capsular bag. If possible, conversion of posterior capsule tears to posterior continuous curvilinear capsulorrhexis (CCC) is recommended.<sup>21</sup> With the use of an OVD, posterior CCC is initiated by grasping the advancing tear in the posterior capsule with forceps, and then applying CCC principles. This technique is applied to avoid an anticipated extension of the inadvertent linear or triangular tear during maneuvers, such as a required vitrectomy or lens placement. The surgeon should ensure that the haptics are orientated away from the rent (to avoid haptic placement or subsequent migration into the vitreous) and that the lens is inserted gently to avoid enlargement of the rent.

#### Iris Fixated (Retropupillary or Prepupillary)

This type of fixation can be chosen for cases of aphakia, defect posterior capsule, or tissue weakness. The great advantage of iris-fixated IOLs is that no capsular bag is necessary for fixation. These lenses, known as *Artisan/Verisyse lenses*, have claws which fix them on the iris stroma and are often implanted in patients with aphakia because of failed cataract surgery, pseudo-exfoliation syndrome (PEX), or connective tissue weakness (Video 5.16.1).

The implantation itself is a difficult technique because of the danger of potential loss of the IOL in the vitreous. Potential complications, such as endothelial cell loss, decentration, loss of enclavation, and iris damage, have to be considered.

Koss and Kohnen found no significant loss of endothelial cells after implantation of anterior chamber iris-claw lenses in aphakic eyes. The distance from lens to endothelium remained constant pre- and postoperatively.<sup>22</sup>

Recent studies have shown an increase in visual acuity after retroiridal or sclerafixated implantation of an IOL due to aphakia, luxation, or zonula insufficiency.<sup>23,24</sup> When implanting IOLs in eyes with zonular insufficiency,

**Fig. 5.16.3 Dropped Nucleus.** B-scan ultrasonography 1 day after dislocation of a lens nucleus into the vitreous cavity in a patient with high myopia.

stabilization with a capsular tension ring has to be considered to avoid further postoperative complications.<sup>25</sup>

Postoperative examinations should include measurement of IOP and endothelial cell count.

#### Ciliary Sulcus

If the rent exceeds 4–5 mm in length or extensive zonular loss occurs, the capsular bag probably is not adequate for IOL support. In such cases, the ciliary sulcus is opened with an OVD, and the iris is retracted in all quadrants to assess the status of the peripheral capsule and zonules. The IOL is inserted with its haptics oriented away from the area of the rent and positioned in areas of intact zonules and capsule.

Another alternative, if the anterior capsulorrhexis is intact, is sulcus placement of the IOL, with capture of the optic through the capsulorrhexis. Finally, some surgeons advocate iris suture fixation of one or both haptics to prevent IOL decentration. After the IOL optic is captured through the pupil, McCannel sutures are used to secure the haptic(s) to the iris, and then the optic is repositioned through the pupil.

#### Sutured Posterior Chamber

If loss of more than 4–5 clock hours of capsule or zonules occurs, the ciliary sulcus may be inadequate for lens stability. The lens can be fixated to the sclera or to the iris using single or dual 10-0 polypropylene or more recently Gore-Tex sutures. If one region of solid peripheral capsule and zonules exists, one haptic can be inserted into the sulcus in this area, and the opposite haptic can be sutured to the sclera or the iris.

#### Anterior Chamber

A Kelman-type multiflex anterior chamber IOL design is a good option for patients who do not have glaucoma, peripheral anterior synechiae, or chronic uveitis. A peripheral iridectomy should be performed in these patients to prevent pupillary block. Iris fixated Artisan anterior chamber type IOLs have even less complications.

### Dropped Nucleus

Loss of nuclear material into the vitreous cavity (Fig. 5.16.3) is one of the most potentially sight-threatening complications of cataract surgery.<sup>26</sup> Clinical and cadaver eye studies implicate posterior extension of breaks in the capsulorrhexis as a common cause of this complication.<sup>7,27</sup> Therefore, the surgeon would be wise to use increased caution when phaco is performed with capsulorrhexis tears.<sup>28</sup> Posterior polar cataract, which predisposes to posterior capsular dehiscence, is another risk factor for dropped nucleus.<sup>29</sup>

Loss of the nucleus into the vitreous cavity can be avoided by recognizing the early signs of posterior capsular rupture. These include unusual deepening of the anterior chamber, decentration of the nucleus, or loss of efficiency of aspiration, which suggests occlusion of the tip with vitreous. If capsular rupture is noted, the steps outlined earlier should be taken to prevent nucleus loss.

Some controversy exists with regard to the appropriate management of loss of the nucleus into the vitreous. Most surgeons recommend completing the procedure with careful anterior vitrectomy and removal of

See clip:  
5.16.1

remaining accessible lens material. In general, IOL implantation is permissible; one exception might be loss of an extremely hard, dense nucleus that would require removal through a limbal incision. If a significant amount of nuclear material has been retained, vitreoretinal surgery needs to be performed 1–2 days postoperatively. Patients whose eyes have small residual nucleus fragments may be observed and referred if increased IOP or uveitis refractory to medical treatment develops. Some surgeons advocate irrigating the vitreous with fluid in an attempt to float the nucleus back into position. An obvious concern is that this additional turbulence could increase vitreous traction on the retina resulting in retinal tears and retinal detachment.

## Anterior Segment Hemorrhage

The presence of intraocular blood prevents the surgeon's visualization during the procedure, stimulates postoperative inflammation, and synechia formation, and accelerates capsular opacification. To minimize the risk of bleeding, discontinuation of anticoagulant therapy before surgery can be considered if it does not pose a significant medical risk to the patient.<sup>30</sup> The sites of anterior segment hemorrhage are either the wound or the iris. Steps to minimize or eliminate bleeding from the wound include the following:

- Careful cautery of bleeding vessels in the vicinity of the incision.
- Creation of an adequate internal corneal valve to minimize the likelihood of scleral blood entering the anterior chamber.
- Performing a clear corneal incision.
- Avoid iris trauma, which can lead to iris bleeding.

Intraocular bleeding can be stopped by taking the following measures:

- Temporarily elevating the IOP with a balanced salt solution or an OVD.
- Injecting a dilute solution of preservative-free epinephrine 1:5000 (or a weaker solution).
- Direct cautery (if the bleeding vessel can be identified) with a needle-tipped cautery probe.

The most serious complication of cataract surgery is expulsive hemorrhage, which is actually a spectrum of conditions ranging from suprachoroidal effusion to mild hemorrhage to severe hemorrhage with expulsion. A sign of any of these conditions is shallowing of the anterior chamber with posterior pressure that resists further deepening of the chamber, sometimes accompanied by a change in the red reflex. These conditions typically occur intraoperatively but also may occur postoperatively, usually when the IOP is below normal (Fig. 5.16.4). Choroidal effusion also may be a precursor to suprachoroidal hemorrhage, which presumably occurs from the rupture of a blood vessel that is placed under stretch. Risk factors for suprachoroidal hemorrhage include hypertension, glaucoma, nanophthalmos, high myopia, and chronic intraocular inflammation.<sup>31</sup>

If sudden shallowing of the anterior chamber occurs and the eye becomes firm, the retina should be examined, if possible, to ascertain the cause. If a dark choroidal elevation is noted, a choroidal hemorrhage is likely, and the incision should be closed as quickly as possible. The worst scenario is expulsion of intraocular contents through the wound. With tunnel incisions, the wound typically is self-sealing and resists expulsion of a significant amount of tissue. This self-sealing construction can save

**Fig. 5.16.4 Choroidal Effusion.** This patient experienced deep ocular pain 1 day postoperatively. A choroidal hemorrhage was noted on close examination. This resolved over several months, leaving no permanent sequelae.

an eye from complete loss of intraocular contents. However, the surgeon can assist by using a finger tamponade on the wound while hyperosmotic solution is given intravenously. The wound should be closed and the anterior chamber deepened further, if possible, using a balanced salt solution or an OVD.

In the event of severe ongoing prolapse of tissue through the incision, a posterior sclerotomy should be performed; this must be done quickly. Time permitting, a conjunctival peritomy is made 3–4 mm posterior to the limbus. Using a microsurgical steel knife, a radial incision approximately 2 mm in length is made, scratching through the sclera to the level of the suprachoroidal space. Usually, blood begins to ooze from this site. As this occurs, infusion of fluid and OVD into the anterior chamber is commenced in an attempt to restore normal anterior segment anatomy. This bleeding site can be left open, or it can be sutured once the rate of hemorrhage has diminished, the incision has been closed, and the normal anterior chamber depth has been restored. The goal in these cases is to preserve the eye; cataract surgery can always be completed at a later date, typically 2 or more weeks later.

It is recommended that postoperative examinations should be performed 1 day, 7–10 days, and 4–6 weeks after cataract surgery.

## POSTOPERATIVE COMPLICATIONS

### Wound Dehiscence

With small-diameter tunnel incisions, wound dehiscence is relatively uncommon. The creation of an internal corneal valve typically prevents the major complications of wound leakage, inadvertent filtering bleb, and epithelial downgrowth. The wound healing process varies according to the site of the posterior entry. Scleral limbal incisions heal by the ingrowth of episcleral vascular tissue. New fibrovascular tissue is deposited with an orientation parallel to the edges of the incision and perpendicular to existing collagen bundles. Over the ensuing few years, collagen remodeling occurs, so that the new collagen becomes oriented parallel to existing collagen bundles, which increases the strength of the healed area.<sup>32</sup> Ultimately, the strength of the healed area is approximately 70%–80% that of the native tissue. For corneal incisions, closure of the external wound takes place by apposition or, in areas of wound gape, by epithelial ingrowth. A gradual process of remodeling then occurs; this consists of fibrocytic metaplasia of keratocytes with deposition of new collagen, again parallel to the incision, followed, over a number of years, by remodeling similar to that seen with scleral incisions. In the absence of vascular tissue, this process occurs much more slowly than in scleral or limbal tissue. Postoperative abnormalities in wound structure are produced by defects in the tunnel architecture or by defective wound healing because of systemic disorders, pre-existing tissue abnormalities (e.g., excessively thin or weak tissue), or incarceration of material, such as lens, vitreous, or iris, in the wound, which inhibits the normal healing process.

### Wound Leakage

A wound leak that occurs in the immediate postoperative period usually is the result of inadequate suture closure for a specific wound configuration. This entity is rare with tunnel constructions. Scleral pocket incisions have a longer tunnel and can readily be demonstrated to be watertight at the conclusion of surgery. Corneal incisions as small as 3.5 mm in width seal remarkably well, even though intraoperative pinpoint posterior lip pressure in these eyes often can induce a wound leak. Some surgeons perform hydration of the corneal stroma to prevent a wound leak that can be elicited with posterior lip pressure; however, this hydration clears within a few minutes to hours, and it is uncertain whether it has any actual clinical value.

Wound leaks in scleral incisions typically are covered by conjunctiva and usually resolve within a few days; occasionally, they lead to the formation of a filtering bleb. Medical management of scleral or corneal wound leaks may include the following:

- Decreasing or discontinuing corticosteroid therapy.
- Administration of prophylactic topical antibiotics.
- Pressure patching.
- Use of a collagen shield, bandage lens, or disposable contact lens.
- Administration of aqueous inhibitors.

It usually is necessary to suture a wound if the leak persists after 5–7 days, or if there is a flat anterior chamber, iris prolapse, extensive external tissue gape, or excessive against-the-wound astigmatism (Fig. 5.16.5).

**Fig. 5.16.5 Wound Dehiscence.** This patient had 5 D of against-the-wound astigmatism following nuclear expression. The surgeon resutured the wound 4 weeks postoperatively, but the astigmatism immediately recurred. Note the thin, fragile sclera, sometimes characterized as scleral “melting.”

### Inadvertent Filtering Bleb

Formation of a filtering bleb after cataract surgery occurs if the wound leaks under a sealed conjunctival flap. If early filtration is recognized, progression might be prevented by discontinuation of corticosteroid treatment. If the patient is asymptomatic, the physician can observe the bleb. Elimination of the bleb can be considered if it causes irritation, tearing, or infection. Blebs that tend to be more symptomatic are tall and cystic and encroach over the corneal surface. Options for late closure include cryotherapy, chemical cautery, neodymium:yttrium–aluminum–garnet (Nd:YAG) laser,<sup>33</sup> or surgical closure. The latter can be a complex procedure because of endothelialization of the fistula. The surgical approach requires excision of the conjunctival bleb, scraping or cryotherapy of the cells that line the fistula, and closure of the fistula, which sometimes requires a scleral patch graft.

### Epithelial Ingrowth

Epithelial ingrowth or downgrowth is a rare but serious complication of intraocular surgery. It occurs most commonly after intracapsular cataract extraction and less often following nucleus expression; it is extremely rare after phaco. Surface epithelium that invades the intraocular structures, such as over the cornea, iris, ciliary body, lens capsule, and Bruch's membrane,<sup>34</sup> can cause corneal decompensation, chronic anterior uveitis, and intractable secondary angle-closure glaucoma. Conditions for the onset of this entity are highly variable, but it appears to be more common in patients who undergo multiple intraocular procedures or have postoperative wound dehiscence.

The presence of epithelial downgrowth may be confirmed by irradiation of the affected iris with an argon laser (epithelial tissue turns white with argon ablation, compared with the dark or brown appearance of normal iris) or diagnosed with specular micrography (noting a sheet of abnormal tissue that obliterates the normal endothelial mosaic); however, the definitive diagnosis is dependent on the histopathological confirmation of epithelial tissue in the eye. Treatment consists of complete destruction of all intraocular epithelial tissue by using cryotherapy, iridocyclectomy, or pars plana vitrectomy. Unfortunately, the prognosis for this postoperative complication is poor, except for a well-defined cyst that can be excised en bloc.<sup>35</sup>

### Postoperative Astigmatism

Complications related to postoperative astigmatism are covered in Chapters 5.4 and 5.18.

### Corneal Edema and Bullous Keratopathy

Factors that predispose to corneal edema following cataract surgery include the following:

**Fig. 5.16.6 Postoperative Hyphema.** This hyphema was produced by hemorrhage from the scleral incision in a patient who had a small postoperative wound leak. The hyphema resolved once the incision closed, which led to cessation of ongoing bleeding and restoration of normal intraocular pressure.

- Prior endothelial disease or cell loss.
- Intraoperative mechanical endothelial trauma.
- Excessive postoperative inflammation.
- Prolonged postoperative elevation of IOP.

Preoperatively, patients should be examined carefully for evidence of Fuchs' dystrophy or other conditions that produce a low endothelial cell count. Patients who have marginal corneal endothelial function may complain of poorer vision in the morning because of corneal edema produced by hypoxia overnight. Although most patients who have Fuchs' dystrophy have guttae that are readily visible with slit-lamp examination, in rare instances, patients can have low endothelial cell counts in the absence of guttae. It often is advisable to obtain an endothelial cell count in the fellow eye. Finally, corneal pachymetry can be helpful to assess such patients because those with a corneal thickness in excess of approximately 0.63 mm presumably have marginally compensated corneas and are at great risk of developing permanent postoperative corneal edema. If the corneal thickness is greater than 0.63 mm but no corneal edema is evident, the authors generally perform cataract surgery alone and advise patients of the increased risk of developing postoperative corneal decompensation. If frank epithelial and stromal edema is present, a combined cataract extraction with posterior lamellar or (only rarely nowadays) penetrating keratoplasty (PKP) may be advisable.

Several measures can be taken intra- and postoperatively to minimize the risk of corneal injury. Some surgeons may consider nuclear expression safer than phaco, and others may consider femtosecond laser-assisted surgery (FLACS) safer.<sup>36</sup> Techniques to remove the nucleus in the posterior chamber seem to minimize endothelial cell loss.<sup>37</sup> Evidence suggests that highly retentive OVDs are more protective when surgical removal of the nucleus is carried out near the endothelium. Postoperatively, inflammation should be aggressively treated with topical corticosteroids, and IOP should be maintained below 20 mm Hg. Mechanical factors, such as Descemet's detachment or retained nuclear fragments in the angle touching the endothelium, should be addressed. For symptomatic relief, hypertonic saline ointment is sometimes helpful as a temporary measure. Sequential corneal pachymetry is an excellent way to document the resolution of postoperative corneal edema, which may take up to 3 months; it is usually advisable to wait at least this long before recommending penetrating keratoplasty.

### Hyphema

A postoperative hyphema is caused by bleeding from the wound or iris (Fig. 5.16.6). As the hyphema resolves, the IOP should be controlled. Surgical reintervention to remove a blood clot is indicated if severe, medically resistant pressure elevation exists for several days. The duration of tolerated pressure elevation depends on the patient's age and the status of the optic nerve. Making clear corneal incisions (CCIs) reduces the incidence of postoperative hyphema.

Late hyphema or microhyphema most often is caused by chafing of the IOL against the iris or ciliary body (uveitis–glaucoma–hyphema [UGH] syndrome).<sup>38</sup> This most typically occurs because of loss of fixation of the sulcus-fixated posterior chamber IOL; micromovements of the lens cause chafing against a vessel, which produces the postoperative bleeding. Treatment consists of IOL exchange and ensuring that the new lens is well fixated; this might require suture fixation to the sclera or implantation of an anterior chamber lens. A rare cause of postoperative bleeding is hemorrhage from vascularization of the internal margin of the incision (Swans syndrome)<sup>39</sup>; this can be diagnosed by noting neovascularization of the wound using gonioscopy; it is treated by argon laser photocoagulation.

## Endocapsular Hematoma

Endocapsular hematoma is the postoperative entrapment of blood between the posterior surface of the IOL and the posterior capsule.<sup>40</sup> It is a variant of hyphema, with the exception that the blood can become entrapped within the capsular bag for months or even permanently. Fortunately, in most instances, the amount of blood is minimal and either does not significantly impair vision or is absorbed over a few weeks or months.<sup>41</sup> When the accumulation is extensive and persistent, Nd:YAG laser posterior capsulectomy is curative when used to enable immediate blood flow into the vitreous, where the blood can be resorbed.

## Intraocular Pressure Elevation

Elevation of IOP following cataract surgery is a common occurrence. Fortunately, it is usually mild and self-limiting and may or may not require prolonged antiglaucoma therapy. Causes of acute pressure elevation are retention of viscoelastic substances, obstruction of the trabecular meshwork with inflammatory debris, and pupillary or ciliary block. Patients who have pre-existing glaucoma are at much greater risk of developing acute, significant pressure elevation. Prevention of this problem includes careful removal of the OVD at the time of surgery, control of intraocular bleeding, and the use of intra- and postoperative antiglaucomatous agents. Intracameral injection of 0.01% carbachol at the conclusion of surgery is effective, as is the postoperative administration of pilocarpine gel; topical beta-blockers; apraclonidine; and topical, intravenous, or oral carbonic anhydrase inhibitors. If marked elevation of IOP is present on the first postoperative day, this can be immediately controlled by “venting” the anterior chamber. After topical anesthetic agents and antibiotics have been administered, a forceps or other fine instrument is used to depress the posterior lip of the paracentesis incision, which allows the egress of a small amount of OVD and aqueous.<sup>42</sup> This is repeated as necessary until the IOP is brought into the low-normal range. The patient can then be treated with topical antiglaucoma therapy and followed carefully to ensure that pressure is controlled.

Chronic IOP elevation can be caused by corticosteroid use, retained lens (particularly nuclear) material, chronic inflammation, peripheral anterior synechiae formation, endophthalmitis, and ciliary block. The correct diagnosis of the underlying cause is required to institute appropriate therapy.

## Capsular Block Syndrome

Capsular block syndrome (CBS) is initially defined as the entrapment of an OVD in the capsular bag because of apposition of the anterior rim of the capsulorrhexis with the anterior face of the IOL.<sup>43,44</sup> This may be more common with acrylic IOLs because of their slightly “stickier” surface. Postoperatively, the bag becomes more distended (perhaps through osmotic imbibition of aqueous), and the IOL is pushed anteriorly to create a myopic refractive shift. This can be prevented by meticulous removal of the OVD from the bag at the conclusion of surgery. To accomplish this, it is helpful to gently depress the IOL optic to displace the OVD trapped behind the IOL.<sup>45</sup> Treatment requires Nd:YAG laser puncture of the anterior capsule peripheral to the edge of the capsulorrhexis, which permits the OVD to escape into the anterior chamber. Alternatively, if the pupil is relatively small and the anterior capsule is not accessible to laser treatment, a small posterior capsulectomy can be performed, which permits the OVD to drain into the vitreous. Another alternative is bimanual aspiration–irrigation of the material from the capsular bag after the IOL has been dislocated with the irrigation instruments.

A new classification of CBS includes intraoperative CBS, early postoperative CBS, and late postoperative CBS.<sup>46</sup> Intraoperative CBS occurs during rapid hydrodissection using a large amount of BSS and has been discussed in the section on hydrodissection. Early postoperative CBS represents the

initial type of CBS, with accumulation of the OVD in the capsular bag, as discussed earlier. Late postoperative CBS refers to eyes with accumulation of a milky-white substance in the closed capsular bag.<sup>47–49</sup> Reduction of vision with this type of CBS is rare, and Nd:YAG laser capsulectomy can be performed, if necessary.

## Intraocular Lens Miscalculation

Complications related to IOL miscalculation are covered in Chapter 5.4.

## Intraocular Lens Decentration and Dislocation

Common causes of IOL decentration and dislocation are asymmetrical loop placement, sunset syndrome, loss of zonular support for a lens fixated in the capsular bag, and pupillary capture of the IOL optic.<sup>50</sup>

### Asymmetrical Haptic Placement

Pathological studies indicate that asymmetrical loop placement is an extremely common occurrence, particularly when “can opener” capsulectomies are performed. The incidence of this complication has been greatly reduced with the advent of capsulorrhexis, which permits excellent visualization of the capsular edge and ensures that a lens placed in the capsular bag is retained there. An IOL with asymmetrical loop placement becomes symptomatic if the lens is decentered sufficiently relative to the pupil; symptoms include polyopia, glare, induced myopia (from looking through the peripheral portion of the IOL), and loss of best spectacle-corrected visual acuity (BSCVA). Depending on the severity of the symptoms, treatment includes IOL repositioning or IOL exchange. In some instances, topical miotics can be prescribed; however, few patients prefer this mode of management.

### Sunset Syndrome

Sunset syndrome occurs when a sulcus-fixated posterior chamber IOL dislocates through a peripheral break in the zonules, typically inferiorly. Sunset syndrome is usually an acute, nonprogressive event. Treatment options again depend on the severity of the patient’s symptoms. The authors have found that simple IOL repositioning is often unsuccessful and predisposes to recurrence. Therefore, several other options are recommended:

- Repositioning the lens, combined with iris fixation sutures.
- IOL exchange with a larger, more rigid lens.
- Scleral fixation of a posterior chamber lens.
- Replacement with an anterior chamber lens.

### Lens-Bag Decentration

In rare instances, a lens that is placed in the capsular bag can dislocate as a result of bag decentration caused by zonular rupture or dehiscence. Treatment of this condition, if sufficiently severe, requires IOL exchange with some form of scleral fixation or implantation of an anterior chamber lens.

### Pupillary Capture

Pupillary capture of the IOL optic consists of the posterior migration of some portion of the iris beneath the IOL optic (Fig. 5.16.7). Predisposing factors are “can opener” capsulectomy and sulcus implantation of the posterior chamber IOL, particularly in the absence of angulated haptics. In rare instances, however, pupillary capture can occur with capsular fixation of the lens after capsulorrhexis, especially when the capsulorrhexis is large.<sup>51,52</sup> Pupillary capture can produce acute and chronic iritis, posterior synechiae formation, visual loss from deposition of inflammatory cells on the IOL surface, and, if the lens is displaced sufficiently eccentrically and anteriorly, chronic endothelial trauma with corneal decompensation. Pupillary capture diagnosed within a few days of its occurrence can be treated pharmacologically or by manually repositioning the optic into the posterior chamber. Chronic pupillary capture may be more difficult to manage, because firm synechiae form between the iris and posterior capsule. In such situations, the IOL should be repositioned if there are visual symptoms, chronic uveitis, or corneal endothelial trauma. Chronic cellular precipitates on the IOL surface can often be managed by the administration of topical corticosteroids and occasional Nd:YAG laser “dusting” of the anterior IOL surface.<sup>53</sup>

## Sulcus-Fixated Intraocular Lens Dislocation

Another subtle but important form of IOL dislocation is loss of fixation of the sulcus-fixated IOL. This can produce recurrent microhyphema or

**Fig. 5.16.7 Pupillary Capture of the Intraocular Lens.** Predisposing factors in this patient included a “can opener” capsulectomy, intraoperative iris trauma, and nonangulated haptics.

hyphema, as well as chronic iritis and even pigmentary glaucoma. The loss of lens fixation often is subtle, but it can be diagnosed at the slit lamp by observing the third and fourth Purkinje images. If the patient is asked to look eccentrically and then refix centrally, these images can be seen to flutter or wobble excessively (pseudo-phacodonesis), which indicates lack of adequate IOL fixation. Intraoperatively, this can be verified by touching the IOL with an instrument; there is obvious IOL instability.

Pigment dispersion syndrome (PDS) can occur after uneventful cataract surgery and implantation of a posterior-chamber single-piece IOL with a sharp-edge design after sulcus position of these IOLs. Several days after IOL implantation, marked pigment dispersion can be seen on the iris and in the trabecular meshwork, associated with an elevation in IOP. Thorough examination showed that the implanted IOL is in the ciliary sulcus. After surgical repositioning of the IOLs into the capsular bag, the pigment dispersion regressed and the IOP returned to normal limits.<sup>54</sup>

## Posterior and Anterior Dislocation

In rare instances, a posterior chamber lens can fall posteriorly and either become suspended in the anterior vitreous (Fig. 5.16.8) or dislocate completely into the vitreous cavity. In the former instance, IOL exchange is advisable, because the lens is within reach and can produce visual symptoms or chafe on uveal tissue. Management of a complete posterior IOL dislocation is more controversial. Although this condition is well tolerated in some eyes, in others, the lenses can become entrapped in the vitreous base and cause vitreous traction and retinal tears, or they can produce visual symptoms by intermittently moving into the visual axis.

Even more rarely, anterior dislocation of a posterior chamber lens into the anterior chamber may occur.<sup>55</sup> This can be prevented with a small and continuous capsulorhexis and in-the-bag implantation of the lens.

## Intraocular Lens Exchange

Several principles of IOL exchange need to be emphasized. It is generally preferable to exchange lenses that have haptics that are poorly designed, too short, or deformed from lens malposition in the eye. Patients who have a marginal corneal endothelium status, generally should be subjected to the least traumatic surgery possible, such as iris repositioning with iris fixation sutures rather than IOL exchange, particularly if the latter requires anterior vitrectomy. It is important to distinguish between IOL decentration and pupil displacement. In some instances, the patient's symptoms result from an eccentrically displaced pupil in the face of a relatively well-positioned IOL. Clearly, surgery, if indicated, should address the underlying problem by reconstructing the pupil. This can be done by suturing the pupil in the peripheral region and opening the pupil centrally with several small sphincterotomies. If certain complications are associated with the site of the dislocated IOL (e.g., recurrent microhyphema with a posterior chamber IOL or peripheral anterior synechiae with an anterior chamber IOL), it may be advisable to place the new lens in a new site.

**Fig. 5.16.8 Intraocular Lens Dislocation.** During surgery, a capsular rupture was noted. A lens was, however, implanted in the posterior chamber. On the morning after surgery, the lens was found to be dislocated posteriorly and inferiorly, and the patient was referred for treatment. At the time of lens exchange, it appeared that insufficient capsular support was present, and a new lens was sutured into the ciliary sulcus.

Finally, if sufficient intact posterior capsule exists, an attempt can be made to reopen the capsular flaps to permit fixation of the new lens within the capsular bag; this, clearly, is the most desirable location.

## Cystoid Macular Edema

Cystoid macular edema (CME) is the most common cause of unexpected visual loss following cataract surgery.<sup>56,57</sup> Fluorescein angiographic CME can occur in up to 50% of patients at 4–8 weeks postoperatively, but clinical CME occurs in less than 3% of patients. Recent studies have shown that macular swelling can be clinically insignificant but can be detected, for example, with optical coherence tomography (OCT).<sup>58</sup> The typical time of onset of clinical CME is 3–4 weeks postoperatively. Predisposing factors are intraoperative complications (e.g., vitreous loss or severe iris trauma), vitreous traction at the wound, diabetic retinopathy,<sup>59</sup> and pre-existing epiretinal membrane. In cases without predisposing factors, CME typically resolves over several weeks, although most surgeons prefer to treat this topically with nonsteroidal and corticosteroid drops.<sup>60</sup> Other modes of treatment that have been employed include sub-Tenon's corticosteroid injection, and administration of systemic nonsteroidal anti-inflammatory drugs with corticosteroids. In patients who have epiretinal membranes, CME may take months to resolve. When associated with diabetic retinopathy, CME often is resistant to medical therapy and can persist indefinitely; macular laser photocoagulation is sometimes helpful to document angiographically the leaking vessels and microaneurysms. Patients who have ongoing structural abnormalities, such as vitreous traction or extensive iris chafing, are less likely to experience spontaneous resolution of CME and may benefit from surgical correction of the precipitating factor.

## Endophthalmitis

Endophthalmitis can occur in an acute or chronic form. It is characterized by ciliary injection, conjunctival chemosis, hypopyon, decreased visual acuity, and ocular pain. The acute form generally develops within 2–5 days of surgery and has a fulminant course (Fig. 5.16.9). Common causative organisms are Gram-positive, coagulase-negative micrococci, *Staphylococcus aureus*, *Streptococcus* species, and *Enterococcus* species.<sup>61,62</sup>

Chronic endophthalmitis is caused by organisms of low pathogenicity, such as *Propionibacterium acnes* or *Staphylococcus epidermidis*. It typically is diagnosed several weeks or longer after surgery. Signs include decreased visual acuity, chronic uveitis with or without hypopyon formation, and, in some instances, plaque-like material on the posterior capsule. Histopathologically, this material consists of the offending microorganism embedded in residual lenticular tissue.

**Fig. 5.16.9 Postoperative Endophthalmitis.** This patient developed acute postoperative endophthalmitis after clear cornea cataract surgery and implantation of a polymethyl methacrylate (PMMA) posterior chamber intraocular lens. During cataract surgery, a capsular break occurred, and an anterior vitrectomy was performed. The patient was treated successfully with vitrectomy and injection of intravitreal antibiotics combined with postoperative topical antibiotic therapy. Final visual acuity was 20/50 (6/15).

Treatment of endophthalmitis consists of culturing aqueous and vitreous aspirates, followed by administration of intravitreal,<sup>63</sup> topical, and subconjunctival antibiotics, as discussed elsewhere. In the Endophthalmitis Vitrectomy Study, no evidence was found of any benefit from the use of systemic antibiotics.<sup>64</sup> Pars plana vitrectomy helped increase the final visual outcome only in those patients who had an initial visual acuity of light perception or worse.<sup>64</sup> (For further discussion of endophthalmitis, see Chapter 7.9.)

## Posterior Capsular Opacification

Secondary cataract formation is a major complication of IOL implantation after extracapsular cataract extraction (ECCE; or phaco). The incidence is in the range of 18%–50% in adults followed up for as long as 5 years; in infants and juveniles, an opacification rate of 44% was found within 3 months of surgery after in-the-bag IOL implantation with an intact posterior capsule.<sup>65</sup> Posterior capsular opacification (PCO) is caused by proliferation and migration of residual lens epithelial cells. These can produce visual loss through two mechanisms:

- Formation of swollen, abnormally shaped lens cells called Elschnig's pearls, which migrate over the posterior capsule into the visual axis (Fig. 5.16.10).
- Transformation into fibroblasts, which may contain contractile elements (myofibroblasts) and cause the posterior capsule to wrinkle (see Fig. 5.16.8).

Standard treatment of PCO consists of opening the capsule with Nd:YAG laser. Complications of this treatment include acute and, in rare instances, chronic IOP elevation, pitting of the IOL, and retinal detachment. Factors that predispose to retinal detachment include an axial length greater than 24.5 mm, male gender, and pre-existing retinal pathology.<sup>66–68</sup>

A related and unusual abnormality is the formation of striae in the posterior capsule in the absence of abnormal proliferation of lens epithelial cells. In some patients, this produces a Maddox-rod effect; the typical symptoms are linear streaks that radiate from lights, and their orientation is 90° from the meridian of the striae. The cause is stretching of the capsular bag by the IOL, which produces the striae aligned with the axis of the lens haptics. Typically, this is present on the first postoperative day but may not be mentioned by the patient until later. In many eyes, the striae resolve in the first or second week after surgery as capsular contraction occurs, which counteracts the stretch forces of the IOL haptics. If the condition persists and is sufficiently symptomatic, it can be corrected readily with a laser posterior capsulotomy. For further discussion of PCO, see Chapter 5.17.

## Retinal Detachment

Retinal detachment is a well-recognized complication of cataract surgery, occurring in 0.2% to 3.6% of persons after extracapsular cataract surgery.

**Fig. 5.16.10 Posterior Capsular Opacification.** Elschnig's pearl formation and capsular wrinkling causing a severe decrease of visual acuity.

The incidence of retinal detachment increases fivefold if an intracapsular procedure is performed.<sup>69</sup> Predisposing factors include Nd:YAG laser capsulotomy, axial length greater than 24.5 mm, myopic refractive error, lattice degeneration, male gender, intraoperative vitreous loss, postoperative ocular trauma, posterior vitreous detachment, and history of retinal detachment in the fellow eye.<sup>67,70,71</sup> Steps to prevent retinal detachment include the following:

- A careful preoperative fundus examination.
- Preservation of the integrity of the posterior capsule at the time of surgery.
- Education of patients with regard to the symptoms of retinal tears and detachment.
- Regular postoperative dilated fundus examinations.

# Secondary Cataract

Liliana Werner

# 5.17

**Definition:** Secondary cataract, also known as *posterior capsule opacification* (PCO), is the most common complication after cataract surgery, resulting from migration and proliferation of residual lens epithelial cells (LECs) onto the central posterior capsule, leading to decrease in visual function, and ultimately in visual acuity. Opacification within the capsular bag also may present as anterior capsule opacification (ACO) or interlenticular opacification (ILO).

## Key Features

- Caused by migration and proliferation of residual lens epithelial cells.
- Treatment is most commonly neodymium:yttrium–aluminum–garnet (Nd:YAG) laser.
- May be exacerbated or ameliorated via surgical techniques and specific lens design.

## INTRODUCTION

Secondary cataract or posterior capsule opacification (PCO) is the most common postoperative complication of cataract surgery. Its incidence has decreased over the past few decades as the understanding of its pathogenesis has evolved. Advances in surgical technique and intraocular lens (IOL) design and materials all have contributed to the gradual decline in PCO incidence. However, it remains a major cause of decreased visual acuity after cataract surgery, occurring at a rate of between 3% and 50% in the first 5 postoperative years.<sup>1</sup>

## PATHOGENESIS

PCO results from migration and proliferation of residual lens epithelial cells (LECs) onto the central posterior capsule. When the cells invade the visual axis as pearls, fibrotic plaques, or wrinkles, the patient experiences a decrease in visual function and, ultimately, in visual acuity.<sup>2</sup> The epithelium of the crystalline lens consists of a sheet of anterior epithelial cells (“A” cells) that are in continuity with the cells of the equatorial lens bow (“E” cells). The latter cells comprise the germinal cells that undergo mitosis as they peel off from the equator. They constantly form new lens fibers during normal lens growth. Although both the anterior and equatorial LECs stem from a continuous cell line and remain in continuity, it is useful to divide these into two functional groups. They differ in terms of function, growth patterns, and pathological processes. The anterior or “A” cells, when disturbed, tend to remain in place and not migrate. They are prone to a transformation into fibrous-like tissue (pseudo-fibrous metaplasia).

In contrast, in pathological states, the “E” cells of the equatorial lens bow tend to migrate posteriorly along the posterior capsule (e.g., in posterior subcapsular cataracts, and the pearl form of PCO). In general, instead of undergoing a fibrotic transformation, they tend to form large, balloon-like bladder cells (the cells of Wedl). These are the cells that are clinically visible as “pearls” (Elschnig’s pearls). These equatorial cells are the primary source of classic secondary cataract, especially the pearl form of PCO. In a clinical study by Neumayer et al., significant changes in the morphology of Elschnig’s pearls were observed within an interval of only 24 hours. Appearance and disappearance of pearls, as well as progression and regression of pearls within such short intervals illustrate the dynamic behavior of regenerative PCO.<sup>3</sup>

The “E” cells also are responsible for formation of a Soemmerring’s ring, which is a doughnut-shaped lesion composed of retained/regenerated cortex and cells that may form following any type of disruption of the anterior lens capsule. This lesion was initially described in connection with ocular trauma. The basic pathogenic factor of the Soemmerring’s ring is the anterior capsular break, which may then allow exit of central nuclear and cortical material out of the lens, with subsequent Elschnig’s pearl formation. A Soemmerring’s ring forms every time any form of extracapsular cataract extraction (ECCE) is done, as manual, automated, or phacoemulsification (“phaco”) procedures. For practical purposes, it is useful to consider this lesion as the basic precursor of classic PCO, especially the “pearl” form. The LECs have higher proliferative capacity in the young compared with the old; therefore, the incidence of PCO formation is higher in younger patients.

The same cell types mentioned above are involved in other processes of opacification within the capsular bag (Fig. 5.171). These include anterior capsule opacification (ACO)<sup>4,5</sup> and interlenticular opacification (ILO).<sup>6,7</sup> The latter is the opacification of the space between two or more IOLs implanted in the bag (piggyback implantation).

## Treatment and Prevention

The treatment of PCO is typically neodymium:yttrium–aluminum–garnet (Nd:YAG) laser posterior capsulectomy. This is a simple procedure in most cases but is not without risks. Complications include IOL damage, IOL subluxation or dislocation, retinal detachment, and secondary glaucoma.<sup>8</sup> Therefore, prevention of this complication is important, not only because of the risks associated with its treatment but also because of the costs involved in the procedure. Extensive research has been performed on the inhibition of LEC proliferation and migration by pharmacological agents through various delivery systems, or IOL coatings, in vitro and in vivo animal studies.<sup>9–11</sup> Use of pharmacological and nonpharmacological agents for this purpose in an unsealed system may increase the risk of toxicity to surrounding intraocular structures, especially corneal endothelial cells. The Perfect Capsule, a silicone device that reseals the capsular bag allowing isolated safe delivery of irrigating solutions into its inner compartment, therefore, was developed.<sup>12</sup> Immunotherapy and gene therapy, as well as physical techniques to kill/remove LECs, have been investigated.<sup>13,14</sup> We evaluated in our laboratory the efficacy of an Nd:YAG laser photolysis system in removing LECs by using eyes from human cadavers. Light microscopy and immunohistochemistry revealed that the laser photolysis system removed LECs from the anterior lens capsule and capsule fornix. Along with the cells, laminin, fibronectin, and cell debris remained in the untreated areas but were removed by the treatment, which may be useful for PCO prevention.<sup>14</sup>

While basic research on an effective mechanism for PCO eradication is evolving, the practical surgeon can apply some principles to prevent it.<sup>15</sup> Studies done in our laboratory, as well as clinical studies done in other centers, have helped in the definition of three surgery-related factors that help in the prevention of PCO:

- Hydrodissection-enhanced cortical cleanup.
- In-the-bag IOL fixation.
- Performance of a capsulorrhexis slightly smaller than the diameter of the IOL optic (Fig. 5.172).

The same studies helped in the definition of three IOL-related factors for PCO prevention:

- Use of a biocompatible IOL to reduce stimulation of cellular proliferation.
- Enhancement of the contact between the IOL optic and the posterior capsule.
- An IOL with a square, truncated optic edge.

**Fig. 5.17.1 Different Forms of Opacification Within the Capsular Bag.** (A) Human eye from cadaver (posterior or Miyake-Apple view) implanted with a rigid lens, showing asymmetric fixation and decentration. A doughnut-shaped, white lesion can be seen for 360° in the equatorial region of the capsular bag (Soemmerring's ring), and the posterior capsule is fibrotic. (B) Human eye from cadaver (posterior view) implanted with a rigid lens. Soemmerring's ring is also present. A posterior capsulotomy had been performed for posterior capsule opacification, and proliferation of Elschnig's pearls can be seen at the edges of the capsulotomy (arrow). (C) Human eye from cadaver (posterior view) implanted with a foldable, plate silicone lens. The anterior capsule is fibrotic (arrow). Although Soemmerring's ring formation can be seen, the posterior capsule is not opacified. (D) Pair of foldable, hydrophobic acrylic lenses explanted because of interlenticular opacification. The lenses are fused together through the material within the interlenticular space.

### Hydrodissection-Enhanced Cortical Cleanup

Howard Fine introduced this technique and coined the term cortical cleaving hydrodissection. The edge of the anterior capsule is slightly tented up by the tip of the cannula while the fluid is injected. The technique is used by many surgeons to facilitate cortex and equatorial LEC ("E" cell) removal, also enhancing the safety of the operation. Experimental studies used different solutions during the hydrodissection step of the phacoprocedure (e.g., preservative-free lidocaine 1%, antimetotics, etc.).<sup>16</sup> Further studies are necessary to establish the safety and utility of these solutions in terms of PCO prevention.

Although a careful cortical cleanup and elimination of as many "E" cells as possible is fundamental to reducing the incidence of PCO, the role of anterior capsule polishing and elimination of "A" cells remains to be demonstrated. Indeed, Sacu et al. have performed a randomized, prospective study to evaluate the effect of anterior capsule polishing on PCO.<sup>17</sup> The anterior capsule was extensively polished in one eye and was left unpolished in the other eye. Digital slit lamp photographs taken 1 year postoperatively by using a standardized photographic technique showed that anterior capsule polishing caused no significant difference in the outcome of PCO. Some authors actually believe that the postoperative fibrous metaplasia of remaining "A" cells would push the IOL against the posterior capsule, and that would explain the relatively low PCO rates of eyes implanted with silicone lenses having rounded optic edges.<sup>18</sup>

### In-the-Bag IOL Fixation

The hallmark of modern cataract surgery is the achievement of consistent and secure in-the-bag or endocapsular IOL fixation. The most obvious advantage of in-the-bag fixation is the accomplishment of good lens

centration. However, endocapsular fixation functions primarily to enhance the IOL-optic barrier effect, as will be discussed later. In a series of human cadaver eyes implanted with different IOLs and analyzed in our laboratory, central PCO and Nd:YAG rates were both influenced by IOL fixation, that is, less PCO and Nd:YAG capsulectomies in eyes where the IOLs were in the bag.<sup>15</sup>

Marie-José Tassignon proposed a variation of the in-the-bag IOL fixation concept for PCO prevention, named "bag-in-the-lens" implantation.<sup>16</sup> This involves the use of a twin-capsulorrhexis IOL design and performance of anterior and posterior capsulorrhexes of the same size. The biconvex lens has a circular equatorial groove in the surrounding haptic, for placement of both capsules after capsulorrhexis. If the capsules are well stretched around the optic of this lens, the LECs will be captured within the remaining space of the capsular bag, and their proliferation will be limited to this space, so the visual axis will remain clear (Fig. 5.17.3). Experimental and clinical studies showed that bag-in-the-lens implantation was highly effective in preventing PCO when the anterior and posterior capsules were properly secured in the IOL groove.

### Capsulorrhexis Size

There is evidence that PCO is reduced if the capsulorrhexis diameter is slightly smaller than that of the lens optic so that the anterior edge rests on the optic. This helps provide a tight fit of the capsule around the optic analogous to "shrinkwrapping," which has beneficial effects in maximizing the contact between the lens optic and the posterior capsule. In a retrospective clinical study performed at the John A. Moran Eye Center, University of Utah, on patients implanted with different IOLs, including lenses with round or square optic edges, the degree of postoperative PCO was

**Fig. 5.17.2 Human Eye Obtained From Cadaver (Posterior View) 19 Months After Implantation of a Single-Piece Hydrophobic Acrylic Lens.** This is an example of application of the three surgery-related factors for prevention of posterior capsule opacification. The lens was symmetrically implanted in the bag, via capsulorrhexis smaller than the optic diameter of the lenses (ideally, the capsulorrhexis margin should cover the edge of the lens for 360°). No significant Soemmerring's ring formation is present.

**Fig. 5.17.3 Clinical Photograph Taken 6 Months After Cataract Surgery With "Bag-in-the-Lens" Implantation in a 64-Year-Old Patient.** The area corresponding to the optic of the lens is completely free of opacities. (Courtesy Dr. Marie-José Tassignon, Belgium.)

correlated with the degree of anterior capsule overlap.<sup>19</sup> Considering all patients, including the patients distributed in different IOL groups, there was always a significant negative, linear correlation between the degree of overlap and PCO.

### Biocompatible Intraocular Lens

Many definitions for the term "biocompatibility" exist. With regard to PCO, materials with the ability to inhibit stimulation of cell proliferation are more "biocompatible." The "sandwich" theory states that a hydrophobic acrylic IOL with a bioadhesive surface would allow only a monolayer of LECs to attach to the capsule and the lens, preventing further cell proliferation and capsular bag opacification. We performed two

immunohistochemical studies on the adhesion of proteins to different IOLs that had been implanted in human eyes from cadavers.<sup>20,21</sup> Analyses of histological sections have demonstrated that fibronectin mediates the adhesion of this hydrophobic acrylic lens to the anterior and posterior capsules. Analyses of explanted lenses have confirmed the presence of greater amounts of fibronectin on the surfaces of the same lens. However, even though differences among materials exist, in terms of PCO prevention it appears that the geometry of the lens, with a square posterior optic edge is the most important factor (see IOL optic geometry below).

The adhesiveness of the material may have a more direct impact on the development of ACO. This generally occurs much earlier in comparison to PCO, sometimes within 1 month postoperatively. When the continuous curvilinear capsulorrhexis (CCC) is smaller than the IOL optic, the anterior surface of the optic's biomaterial maintains contact with the adjacent posterior aspect of the anterior capsule. Any remaining anterior LECs ("A" cells) in contact with the IOL have the potential to undergo fibrous proliferation; thus, ACO is essentially a fibrotic entity. Studies in our laboratory using pseudo-phakic eyes obtained from cadavers showed that ACO is more common with silicone IOLs, especially the plate designs, because of the larger area of contact between these lenses and the anterior capsule (see Fig. 5.171C).<sup>4</sup> However, the same studies showed that the plate design resists contraction forces within the capsular bag better than three-piece silicone lenses with flexible haptics (polypropylene).<sup>5</sup> These latter showed the higher rates of capsulorrhexis phimosis and IOL decentration as a result of excessive capsular bag fibrosis. Therefore, a tendency exists in IOL manufacture favoring haptic materials with higher rigidity, such as polymethyl methacrylate (PMMA), polyimide (Elastimide), and poly(vinylidene) fluoride (PVDF). In the same studies, ACO was less significant with hydrophobic acrylic lenses having an adhesive surface.

ACO has been considered a clinical problem when anterior capsular shrinkage associated with constriction of the anterior capsulotomy opening (capsulorrhexis contraction syndrome or capsular phimosis) accompanies excessive anterior capsule fibrosis. This has been especially observed in conditions associated with zonular weakness (e.g., pseudo-exfoliation and advanced age, and with chronic intraocular inflammation. Besides phimosis of the CCC opening, excessive zonular traction, and its sequelae, IOL dislocation and retinal detachment can occur because of excessive capsular fibrosis. Excessive opacification of the anterior capsule is problematic in that it hinders visualization of the peripheral fundus during retinal examination. Otherwise, a certain degree of ACO is sometimes considered an advantage because it can prevent potential dysphotopsia phenomena caused by the square edge of some IOL optic designs. Additionally, anterior capsule fibrosis with contraction of the capsular bag will push the IOL optic against the posterior capsule, helping in the prevention of PCO according to the "no space, no cells" theory. This mechanism would explain the relatively low PCO rates with some silicone lenses, in the absence of a square optic edge profile, as noted above (hydrodissection-enhanced cortical cleanup).<sup>18</sup>

The adhesiveness of the IOL material may also have an influence on ILO formation. To date, all cases of ILO that we have analyzed in our laboratory seem to be related to two hydrophobic acrylic IOLs being implanted in the capsular bag through a small capsulorrhexis, with its margins overlapping the optic edge of the anterior IOL for 360°.<sup>6</sup> When these lenses are implanted in the capsular bag through a small capsulorrhexis, the bioadhesion of the anterior surface of the front lens to the anterior capsule edge and of the posterior surface of the back lens to the posterior capsule prevents the migration of the cells from the equatorial bow onto the posterior capsule. This migration may be directed toward the interlenticular space. In this scenario, the two IOLs are sequestered together with aqueous and LECs in a hermetically closed microenvironment. In addition, the adhesive nature of the material seems to render the opacifying material very difficult to remove by any surgical means (see Fig. 5.171D).

Based on the common features of different cases of ILO, some surgical methods were proposed for its prevention. The first option would be to implant both IOLs in the capsular bag but with a relatively large-diameter capsulorrhexis. The other possibility is to implant the anterior IOL in the sulcus and the posterior IOL in the bag with a small rhexis. These should help sequester the retained/proliferated equatorial LECs within the equatorial fornix. Reassessment of factors leading to ILO formation is important because of the development of dual-optic accommodating IOLs to be implanted in the capsular bag.<sup>7</sup> Additionally, piggyback implantation for correction of residual refractive errors appears to be increasing in popularity, including implantation of a multifocal IOL in patients with pseudo-phakia. However, in these cases the second (anterior) IOL is generally fixated in the ciliary sulcus.

**Fig. 5.17.4 Foldable, Hydrophilic Acrylic Lenses With Square Optic and Haptic Edges.** The lens in (B) was modified to incorporate an extra ridge all around the optic (enhanced square edge; arrow). (C,D) are photographs obtained from rabbit eyes (posterior view), experimentally implanted with the lenses in (A,B), respectively. Soemmerring's ring formation is observed in both eyes. The arrow in (C) shows the opacification of the posterior capsule, which started at the level of the optic-haptic junction. (From: Werner L, Mamalis N, Pandey SK, et al. Posterior capsule opacification in rabbit eyes implanted with hydrophilic acrylic intraocular lenses with enhanced square edge. *J Cataract Refract Surg* 2004;30:2403–9.)

### Contact Between the IOL Optic and the Posterior Capsule

Different factors can help maximize the contact between the IOL and the posterior capsule, contributing to the so-called “no space, no cells” concept. Optic/haptic angulation displacing the optic posteriorly and stickiness of the IOL optic material are the most important lens features for obtaining a tight fit between lens and capsule. Three-piece lenses manufactured from the different haptic materials currently available today have in general a posterior optic/haptic angulation ranging 5°–10°. To keep the advantages of the two above-mentioned factors, it is important to achieve endocapsular lens fixation and to create a capsulorrhexis smaller than the diameter of the lens optic.

Capsular tension rings may have a role in the prevention of PCO. Equatorial capsular tension rings have the ability to maintain the contour of the capsular bag and to stretch the posterior capsule. Thus, they have primarily been used in cases of zonular rupture or dehiscence, secondary to trauma, or when inherent zonular weakness is present, such as in pseudo-exfoliation syndrome. It has been demonstrated by high-resolution laser interferometric studies that a space exists between the IOL and the posterior capsule with different lens designs. With a capsular tension

ring in place, this space was found to be smaller or nonexistent. Thus, LECs would not find a space to migrate and proliferate onto the posterior capsule. Capsular tension rings also produce a circumferential stretch on the capsular bag, with the radial distention forces equally distributed. Formation of traction folds in the posterior capsule, which may be used as an avenue for cell ingrowth is thus avoided.

Capsular tension rings may also have a role in the prevention of opacification of the anterior capsule. The presence of a broad, band-shaped, capsular ring would keep the anterior capsule leaf away from the anterior optic surface and the posterior capsule. This would ultimately lead to less metaplasia of LECs on the inner surface of the anterior capsule with less fibrous tissue formation, as well as less opacification and contraction of this structure. IOLs with design features that also help maintaining the anterior capsule away from the anterior surface of the lens have been evaluated in our laboratory.<sup>7</sup> A capsular tension ring designed to prevent opacification within the capsular bag was evaluated in two centers, one in Japan (Nishi O) and the other in Austria (Menapace R).<sup>22</sup> Both centers reported a significant reduction in PCO and ACO with the rings, in comparison to the contralateral eyes implanted with the same lens design.<sup>22</sup>

### Intraocular Lens Optic Geometry

The square, truncated lens optic edge acts as a barrier, preventing migration of proliferative material from the equatorial region onto the posterior capsule.<sup>15</sup> The barrier effect is absent in lenses having rounded edges, and proliferative material from the equatorial region has greater free access to the posterior capsule, opacifying the visual axis. The barrier effect of the square optic edge is functional when the lens optic is fully in the bag, in contact with the posterior capsule. When one or both haptics are out of the bag, a potential space that is present allows an avenue for cellular ingrowth toward the visual axis. Different modern lenses manufactured from different materials currently on the market present this important design feature. Some of them have a square edge on the posterior optic surface, whereas the anterior optic edge has remained round to prevent dysphotopsia. Findings from experimental studies which demonstrate that the square edges of different lenses on the market are not equally “sharp,” even when the same class of materials is considered, are noteworthy.<sup>23,24</sup>

The optic-haptic junctions of square-edged single-piece lenses may represent a site for cell ingrowth and PCO formation.<sup>25</sup> At the level of those junctions, the barrier effect of the square edge appears to be less effective. We obtained better results regarding PCO formation with a hydrophilic acrylic single-piece lens having an “enhanced” square edge than with the standard model of the same design.<sup>25</sup> The enhanced edge provided the lens with a peripheral ridge around the lens optic for 360°. In the standard model, the square edge profile appeared to be absent at the level of the optic-haptic junctions (Fig. 5.174<sup>26</sup>). Therefore, the square optic edge is probably the most important IOL design feature for PCO prevention. It appears, however, that it should be present for 360° around the IOL optic in order to provide an effective barrier effect.

### INTRAOCULAR LENSES MAINTAINING THE CAPSULAR BAG OPEN OR EXPANDED

We have recently evaluated the outcome of capsular bag opacification with a new single-piece, disc-shaped hydrophilic acrylic IOL compared with a commercially available single-piece, hydrophobic acrylic IOL in the rabbit eye for 5 weeks (Fig. 5.175).<sup>27,28</sup> The peripheral rings of the disc-shaped lens, by expanding the capsular bag and preventing IOL surface contact with the anterior capsule, prevented ACO and PCO. We hypothesized that IOL designs maintaining an open or expanded capsular bag are associated with bag clarity. Mechanical compression of the inner bag surface (and residual LECs) by a relatively bulky device/IOL has been one of the possible mechanisms advanced to explain this finding. Another factor may be mechanical stretch of the bag at the level of the equatorial region (maintaining the overall bag contour), by some devices, such as the capsular bending ring of Nishi and Menapace,<sup>22</sup> and Hara’s equator ring.<sup>29</sup> Constant irrigation of the capsular bag’s inner compartment by the aqueous humor also may have an influence on the prevention of proliferation of residual LECs. Equatorial stretch and aqueous humor irrigation would help explain the PCO preventative effect, even in eyes where there was no contact between the IOL optic and the posterior capsule. Previous reports indicated that transforming growth factor- $\beta_2$  in the normal aqueous humor inhibits proliferation of LECs and corneal endothelial cells.<sup>30</sup> According to Nishi, constant irrigation by the aqueous humor may prevent certain cytokines that are involved in stimulating LEC proliferation from reaching a threshold concentration level within the bag compartment; one of these cytokines would be represented by interleukin-1.<sup>31</sup>

In summary, development of PCO is multifactorial, and its eradication depends on the quality of the surgery as well as on the quality of the IOL implanted. Each factor described here does not act in isolation; it is their interaction that produces the best results. Research on the prevention of any form of opacification/fibrosis within the capsular bag is increasing in importance, especially with the advent of specialized IOLs, such as accommodative lenses, which are designed to enable a forward movement of the optic on efforts of accommodation. The functionality of such lenses will likely require the long-term transparency and elasticity of the capsular bag. Further research to investigate new proposed mechanisms for capsular bag opacification prevention, such as with IOLs/devices maintaining an open capsular bag, is warranted.

**Fig. 5.175 Gross Photograph (Miyake-Apple View) of the Anterior Segment of a Rabbit Eye Implanted With a New Disk-Shaped IOL, Taken 5 Weeks Postoperatively.** The lens is a single-piece, hydrophilic acrylic, monofocal lens suspended between two complete haptic rings that are connected by a pillar of the haptic material. This design maintains the capsular bag expanded, with the anterior capsule separated from the anterior optic surface. Anterior and posterior capsules are overall clear. Minimal proliferation is limited to the space between the peripheral rings.

# Outcomes of Cataract Surgery

Mats Lundström

# 5.18

**Definition:** Outcomes of cataract surgery include both objective and subjective measures. The objective outcomes are typically visual and refractive.

## Key Features

Objective measures of functional vision:

- Uncorrected visual acuity.
- Best-corrected visual acuity.
- Contrast sensitivity.
- Glare disability.
- Visual field.
- Color vision.

## INTRODUCTION

Outcomes of cataract surgery can be classified according to objective and subjective findings. Objective measures of functional vision include not only best-corrected visual acuity (BCVA) but also uncorrected distance visual acuity, contrast sensitivity, glare disability, visual field, and color vision. The refractive outcome is important because a cataract extraction is also a refractive procedure. Subjective findings are best evaluated through structured interviews or questionnaires.

## EVALUATION OF OUTCOMES

Functional vision assessment implies the ability to characterize parameters of vision and translate these into how well a patient is able to perform activities in daily life with respect to vision. To do this objectively, the parameters that characterize vision must first be determined. In both clinical practice and research, these parameters can be allocated to five major areas:

- Limiting resolution (high-contrast visual acuity).
- Contrast performance (contrast sensitivity and threshold).
- Performance at various background illuminations (glare disability).
- Field of view (visual field).
- Color performance (color vision).

It is important to fully evaluate the visual system in a patient who has a cataract by using these five parameters. In many cases, the patient does not present to the clinician with the diagnosis of cataract. The patient usually presents with complaints of decreased vision or visual disabilities. It is the clinician's responsibility to evaluate the patient's history and examine the patient to determine the cause of the reduced vision. After diagnosis of a cataract—or any other diagnosis—has been made, some of the five parameters that describe visual performance may be found to be less important.

To translate the visual performance or functional vision of a patient into the ability to perform a specific activity necessitates knowledge of the visual requirements needed to carry out that activity. The visual requirements needed to perform specific daily life activities are poorly mapped out. Therefore, the patient's self-assessed limitation in carrying out daily life activities that are dependent on vision is an important part of the outcomes evaluation. It has been suggested that self-assessed visual function is the most important part of the outcomes evaluation.<sup>1</sup> In the evaluation of outcomes of cataract surgery in daily practice, a proper follow-up time after surgery is crucial. Just as status 1 day after surgery may reflect whether the surgery was traumatic or not, sufficient time must elapse before the final refraction and patient satisfaction can be evaluated. The visual outcome

depends on the surgical procedure, the age of the patient, ocular comorbidities, and surgical complications, among other things. The refractive outcome depends on the surgical procedure, the preoperative status and examination, and the intended target refraction. The type of intraocular lens (IOL), pupil size, and surgical procedure are important for contrast sensitivity, glare, halos, and other visual disturbances. The patient's satisfaction with vision after surgery depends on the preoperative information given and the patient's expectations, as well as the visual outcome.

## FIVE PARAMETERS THAT DESCRIBE VISUAL FUNCTION

### Visual Acuity Testing

#### Standardized Visual Acuity Testing

Standardized visual acuity tests measure the ability of a patient to recognize standardized optotypes (usually Snellen acuity letters) at a specified visual angle, illumination, and contrast.<sup>2</sup> Visual acuity can be recorded in various notations, in which normal vision would be Snellen units 20/20 or 6/6, decimal notation 1.0, or logarithm of minimum angle of resolution (LogMAR) 0.0.

#### Potential Retinal Acuity Testing

A special type of acuity test used in cataract patients is the assessment of potential retinal acuity. This test is essential for patients who have pigment mottling in the macula and reduced vision, particularly in the presence of a cataract or other optical aberrations of the eye. In the cataract age group, the incidence of macular degeneration is at least 10% and may exceed 15%, depending on the age of the patient.<sup>3,4</sup> It is important that both the surgeon and the patient have a realistic expectation of the quality of postoperative vision, which helps both parties to accurately assess the risk-benefit ratio. Removal of a significant cataract always should be considered, even in the presence of an abnormal macula or if the predicted acuity is low.

### Contrast Sensitivity Testing

Contrast sensitivity testing is important for the assessment of both sensory disease and media opacities. With media opacities, such as cataracts, a general depression occurs in contrast sensitivity at all points, with a slightly greater depression at lower contrasts.<sup>5-7</sup>

### Glare Testing

Glare testing is useful in the assessment of media opacities, such as cataracts. The effects are negligible in sensory disorders, except for a few macular disorders, such as cystoid macular edema (CME), in which intraocular light scatter occurs in the superficial layers of the retina.<sup>8,9</sup> Even with this disorder, the changes in glare disability are minimal. Glare testing can be very sensitive and specific to media opacities, but more importantly, it gives visual acuity values or equivalents that relate to a person's vision in daylight, as opposed to vision in a testing room with high-contrast letters.

### Visual Fields

The integrity of visual fields is particularly important in patients with sensory disorders, such as glaucoma and optic neuropathies, and patients who have suffered strokes that have affected the visual pathways.<sup>10,11</sup> Unfortunately, these disorders also are common in the age group that suffers from cataracts and may go undetected until after the cataract surgery. Additionally, visual field defects that result from strokes may change the

risk–benefit ratio for cataract surgery, particularly if the stroke occurred recently.

## Color Vision

Color vision is specifically important in sensory disease, such as retinopathies and optic neuropathies, which often show characteristic color vision changes that help make the differential diagnosis and monitor the effect of therapy. In patients who have ocular media disorders, such as cataracts, the changes in color vision can usually be correlated with the color of the cataract. For example, a patient who has a brunescient (yellow-brown) cataract has significant deficiencies in the blue end of the visual spectrum (shorter wavelengths).<sup>12</sup> When color deficiencies do not correlate, sensory disorders should be suspected. Although color vision testing is very sensitive in some disorders, such as central serous maculopathy and CME, by “bleaching” or reducing the apparent brightness, other parameters, such as visual acuity, visual field, and contrast sensitivity, are also affected, which makes routine color testing unnecessary.

## OBJECTIVE FINDINGS OF CATARACT SURGERY OUTCOMES

### Best-Corrected Visual Acuity

The term *best-corrected visual acuity* implies that the patient’s eye has been optically corrected to achieve the best visual acuity. In most cases, this value is obtained with best spectacle refraction. In cases of irregular corneal astigmatism, the BCVA may be attained with a rigid contact lens, not with spectacles. In recent studies with known preoperative pathology excluded (best case analyses), between 97% and 98% of the patients who had received cataract surgery achieved BCVA equal to or better than 20/40 (6/12; 0.5).<sup>4,13</sup> A suggested standard was to achieve a final BCVA of 0.5 or better in 97% of all cataract extractions in eyes with no ocular comorbidity.<sup>4</sup> The corresponding number for all routine patients with cataract, including those with ocular comorbidity, was 94% in a recent report (Table 5.18.1).<sup>4</sup>

### Uncorrected Visual Acuity

The term *uncorrected visual acuity* (UCVA) refers to the patient’s vision in standard conditions with no extraocular optical correction. Unlike BCVA, several additional factors (e.g., pupil size, degree of refractive error, and amount of regular astigmatism) also influence the measured visual acuity.<sup>14–16</sup> UCVA is most useful in the evaluation of specialty lenses, such as multifocal and toric intraocular lenses (IOLs). The goal when using these lenses is to reduce or eliminate the patient’s dependence on glasses and to achieve good uncorrected distance visual acuity (UCDA) and near visual acuity. To achieve target refraction is crucial when using multifocal IOLs. Unfortunately, multifocal IOLs have a tendency to give more glare and halo compared with monofocal IOLs.<sup>17</sup> This applies to most types of IOLs with more than one focus, and to construct the optimal IOL for both near and distant vision is an area of active research. UCVA can be used as a quality characteristic of the surgical procedure, especially on the day after surgery.<sup>18</sup> For this purpose, however, it is relevant to use the target refraction if, for instance, postoperative myopia is planned.

### Target Refraction Prediction Error

Another factor in the determination of UCVA is the ability to achieve the target postoperative refraction. Most surgeons target the majority of their patients for postoperative refractions in the range of 0.0 to –0.50 D. With modern biometry equipment, newer IOL formulas, personalization of lens constants, and improvements in surgical technique, at least 90%

of patients should have sphero-equivalent refraction within  $\pm 1.00$  D of the intended target.<sup>19</sup> In a recent study on routine cataract surgery, about 90% of cataract extractions resulted in a final refraction within  $\pm 1.0$  D of the intended target refraction (see Table 5.18.1).<sup>4</sup> A suggested standard was a biometry error with a correct sign centered on 0 D and with 87% or more of the values within  $\pm 1$  D of error.<sup>4</sup>

Surgically induced astigmatism (SIA) may be intentional or not intentional. Small-incision cataract surgery results in less SIA than did earlier, larger-incision surgical techniques.<sup>20–22</sup> The magnitude of SIA may be less than 0.5 D on average, depending on incision site and incision size.<sup>23–25</sup> The best outcome of cataract surgery with respect to astigmatism is usually to achieve as low a postoperative astigmatism as possible. SIA can be used to achieve this result by varying the placement of the incision. SIA, thereby, can counteract preoperative astigmatism and result in reduced postoperative astigmatism.<sup>26,27</sup>

## Contrast Sensitivity

Following cataract surgery, in the absence of other ocular disease, the contrast sensitivity returns to normal.<sup>28,29</sup> Binocular contrast sensitivity may not be normalized until second eye surgery has been performed, given the occurrence of cataract in both eyes.<sup>30</sup>

## Glare

Studies have documented that the correlation of most of the instruments used for glare testing and outdoor vision testing show a dramatic improvement after cataract surgery.<sup>6,7,31–34</sup>

## Visual Fields

The visual field returns to normal after cataract surgery in the absence of ocular comorbidity.

## Color Vision

After cataract surgery in patients who have blue-color deficiencies caused by the cataract, the return to normal color vision is perceived as sensational by some patients but is not even noticed by others. Color vision returns to normal in the absence of other ocular disease.

## SUBJECTIVE FINDINGS OF CATARACT SURGERY OUTCOMES

### Patients’ Self-Assessment of the Visual Outcome

A large number of questionnaires for use in cataract surgery care have been published.<sup>35</sup> They usually cover activity limitations in daily life because of problems with vision and, therefore, are disease-specific questionnaires for establishing the health-related quality of life for cataract patients. On average, about 90% of patients undergoing cataract surgery achieve improved self-assessed visual function, according to a multicenter study using a modern questionnaire (see Table 5.18.1).<sup>36,37</sup>

Older patients (>85 years) also benefit from cataract surgery.<sup>38,39</sup> The positive impact of cataract surgery on patients’ self-assessed visual function seems to be long lasting, provided that no other ocular disease appears in the operated eye.<sup>40,41</sup> Self-assessed poor visual function after cataract surgery may result from an ocular comorbidity, a disturbing cataract in the fellow eye, or anisometropia.<sup>42</sup> Several factors are related to better subjective visual outcome. These include younger age, low preoperative visual acuity, high postoperative visual acuity, second-eye surgery, and no ocular comorbidity.<sup>43</sup>

## CATARACT SURGERY OF ONE OR BOTH EYES

Patients with bilateral cataract benefit from bilateral cataract extraction. Studies have shown that second-eye cataract surgery adds health-related quality of life for such patients.<sup>44,45</sup> A remaining cataract in the fellow eye after first-eye surgery may have a poor effect on binocular vision.<sup>30,42</sup>

A bilateral cataract extraction can be performed sequentially with a varying interval between the two surgeries so that some patients receive immediate sequential cataract surgery (ISCS), while others have delayed sequential cataract surgery (DSCS) with an interval between the surgeries of weeks or months. However, same-day bilateral cataract surgery requires

**TABLE 5.18.1 Outcome Measures Following Cataract Surgery: Achievements in Some Recent Studies (%)**

Measure	All Patients	Best Cases
BCVA $\geq 0.5$ (6/12)	94 <sup>4</sup>	97 <sup>13</sup>
Absolute mean prediction error $\leq 1$ D	91.5 <sup>4</sup>	97.3 <sup>4</sup>
Better patient reported visual function after surgery than before	91.5 <sup>37</sup>	
BCVA, best-corrected visual acuity.		

a strict set of operating rules, whereby each eye is treated as an entirely new operative procedure to avoid any possibility of cross contamination. Rapid rehabilitation of the patient is a worthy goal and a more economic process for all concerned.<sup>46</sup>

CATARACT SURGERY IN EYES WITH OCULAR COMORBIDITY

A substantial number of patients undergoing routine cataract surgery have coexisting eye diseases. A sight-threatening ocular comorbidity is the most frequent reason for a poor outcome after cataract surgery.<sup>21,42,47-51</sup> However, this does not mean that cataract extraction is unnecessary when there is an ocular comorbidity. Studies have shown that many patients with age-related macular degeneration and cataract benefit from cataract extraction.<sup>52,53</sup>

SUMMARY

All clinicians are aware that good history taking, a thorough examination, and quantification of the five areas that describe functional vision are all important in the determination of indications for surgery and outcome of surgery. Furthermore, it is extremely important to evaluate the indications for, and outcomes of, cataract surgery with respect to health-related quality of life. This is in the best interests of patients, but it should also be done because of the significant costs to health care linked to this procedure.

# Structure of the Neural Retina

Hermann D. Schubert

## 6.1

**Definition:** The structure of the neural retina reflects its embryological development and its ultimate purpose: the absorption and processing of photons of visible light.

### Key Feature

- In a surgical specialty, knowledge of anatomy has to keep pace with that of imaging and procedures.

### INTRODUCTION

The primary purpose of the corneoscleral and uveal coats of the eye is to provide protection to the retina in addition to providing nourishment and enabling ocular movement. The retina is derived embryologically from the optic vesicle, an outpouching of the embryonic forebrain.<sup>1</sup> The bilayered neuroepithelial structure of the mature retina reflects the apex-to-apex arrangement of the original optic cup. It also forms the wall of a cavity, the vitreous cavity, which is filled with glycosaminoglycans and collagen. The ocular cavity is homologous to a leptomeningeal cistern<sup>2</sup> in that both vitreous and choroid are derived from mesenchyme that sandwiches the neuroepithelium on its path away from the brain. The ocular neuroepithelial cyst has two openings. Anteriorly lies the pupil, which is a full-thickness aperture, and posteriorly lies the optic nerve in which, similar to a coloboma, only derivatives of the inner retinal layers are found. Because the cell apices are oriented inwardly, the two layers of the optic cup and their derivatives are enveloped externally by basement membrane (Fig. 6.1.1).

The relationship of the epithelial layers to each other is modified from anterior to posterior. Anterior to the ora serrata, the pigmented and nonpigmented epithelia of the iris and ciliary body are joined at their apices by a system of intercellular junctions (Fig. 6.1.2), which is continuous with the external limiting layer of the neural retina and the apical junctional girdles

of the retinal pigment epithelium (RPE; Fig. 6.1.3). At the ora serrata, the pigmented epithelium is continued as RPE; its basement membrane becomes Bruch's membrane. The nonpigmented epithelium of the ciliary body and pars plana is continued posteriorly as the neural retina; its basement membrane becomes the internal limiting membrane. The union of the epithelial layers delimits the anterior cul-de-sac of the subretinal space at the ora serrata.<sup>3</sup>

The apex-to-apex arrangement between the epithelia that clearly exists anterior to the ora is continued posteriorly by Müller cells that face and

**Fig. 6.1.1 Apex-to-Apex Arrangement of Müllerian Glia and Retinal Pigment Epithelial Cells.** Because the cell apices face each other, the neuroepithelia are enveloped externally by a basement membrane. Note that this basement membrane is elaborated by a single-layer neuroepithelium, in contrast to the internal limiting membrane, which is formed by Müller cells.

**Fig. 6.1.2 Apex-to-Apex Arrangement of Retina and Pigment Epithelium.** Apical attachments connect the iris and ciliary body epithelia (red dotted line).

**Fig. 6.1.3 Transition of Neural Retina to Nonpigmented Epithelium at the Ora Serrata.** The external limiting membrane, which consists of the attachment sites of photoreceptors and Müller cells, transforms into the apical junctional system of the pars plana epithelia. The internal limiting membrane becomes the basement membrane of the nonpigmented epithelium.

## STRUCTURES OF THE RETINA THAT BORDER THE OPTIC NERVE HEAD

**Fig. 6.1.4 Structures of the Retina That Border the Optic Nerve Head.** The junctional system of the external limiting membrane connects with the apical junctional system of the retinal pigment epithelium and is supported by the intermediary border tissue of Kuhnt.

intermittently contact the RPE (see Fig. 6.1.1). Here, the contact is maintained not by apical junctions (even though an interreceptor matrix exists) but by the pressure of the vitreous and by suction forces of the RPE. Müllerian glia are the main structural cells of the neural retina and are found throughout the retina from the ora to the optic nerve head.

At the optic nerve head, the internal limiting membrane continues as the basement membrane of Elschnig, supported by the glial meniscus of Kuhnt (Fig. 6.1.4). The (glial) external limiting membrane joins the apices of the RPE to form the posterior cul-de-sac of the subretinal space at the optic nerve,<sup>3</sup> which is delimited by a glial border tissue, the intermediary border tissue of Kuhnt. This border tissue continues posteriorly at the choroidal level as the border tissue of Elschnig; both tissues separate the outer retina and choroid from the axons of the inner retina. The axons, in turn, fixate the posterior retina to the scleral lamina cribrosa and its glial system. The retina, therefore, is fixed to the choroid directly by the apical junctional system at the ora serrata (anterior cul-de-sac of the subretinal space) and indirectly, via the ciliary body and choroid, to its attachments at the scleral spur and sclera. At the nerve head, all neuroepithelial and choroidal layers are fixed by both the junctional tissues and the exiting axons. The corneoscleral coat protects, moves, and holds the retina in the appropriate position and allows the object of regard to be focused on the center of the retina.

## CENTER OF THE MACULA: UMBO

The fovea represents an excavation in the retinal center and consists of a margin, a declivity, and a bottom (Fig. 6.1.5). The bottom corresponds to the foveola, the center of which is called the *umbo*. The umbo represents the precise center of the macula, the area of retina that results in the highest visual acuity. Usually, it is referred to as the *center of the fovea* or *macula*. Although both terms are commonly used clinically, neither is a precise anatomical designation.

The predominant photoreceptor of the foveola and umbo is the cone. The foveal “nuclear cake” results from the centripetal migration of the photoreceptors and the centrifugal lateral displacement of the bipolars and ganglion cells during foveal maturation, which occurs 3 months before and 3 months after term.<sup>4,5</sup> Although their individual diameters are narrowed because of extreme crowding, central cones maintain their volume through elongation, up to a length of 70  $\mu\text{m}$ .<sup>5</sup> The central packing of cones takes place in an area of 1500  $\mu\text{m}$  diameter.<sup>4</sup> The greatest concentration of cones is found in the umbo, an area of 150–200  $\mu\text{m}$  diameter, referred to as the *central bouquet of cones*.<sup>5</sup> Estimates of central cone density are 113 000 and 230 000 cones/ $\text{mm}^2$  in baboons and cynomolgus monkeys, respectively. For the central bouquet, the density of cones may be as high as 385 000 cones/ $\text{mm}^2$ .<sup>6</sup> The inner cone segments (myoids) are connected

## FOVEAL MARGIN, FOVEAL DECLIVITY, FOVEOLA, AND UMBO

**Fig. 6.1.5 Foveal Margin, Foveal Declivity, Foveola, and Umbo.** The foveal diameter (from margin to margin) measures 1500  $\mu\text{m}$ , and the foveola is 350  $\mu\text{m}$  in diameter. The foveal avascular zone is slightly larger (500  $\mu\text{m}$ ) and is delimited by the capillary arcades at the level of the inner nuclear layer. The foveal excavation represents the fovea interna, which is lined by the internal limiting membrane. The fovea externa is represented by the junctional system of the external limiting membrane. Both fibers of Henle and the accompanying glia assume a horizontal and radial arrangement in the fovea.

## UMBO AND FOVEOLA

**Fig. 6.1.6 Umbo (Center) and Foveola.** The outer nuclear layer is separated from the inner nuclear layer by the horizontal-oblique fibers of Henle. Umbo and foveola between few nuclei feature clear müllerian fibers (clear tissue), delimited by fibers of Henle externally and by the internal limiting membrane internally. The central 150–200  $\mu\text{m}$  represents the umbo, where cone concentration is maximal.

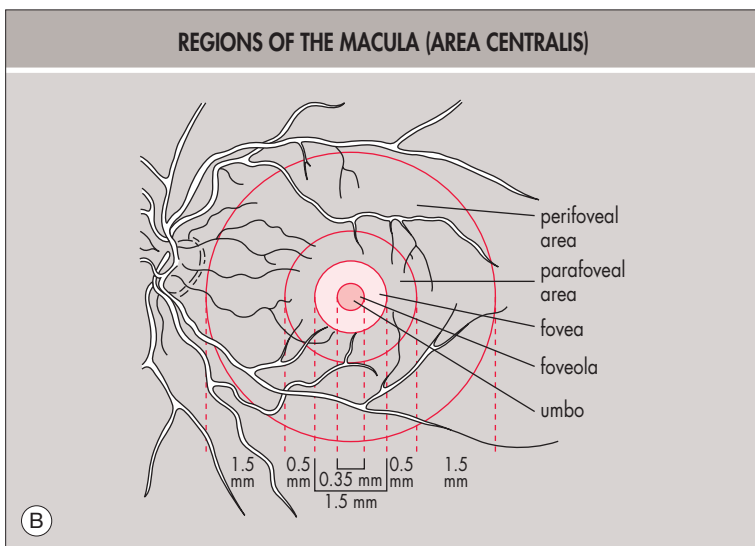

laterally by a junctional system, the external limiting membrane. Their inner fibers (axons) travel radially and peripherally as fibers of Henle in the outer plexiform layer (Fig. 6.1.6). As a result of their high concentration and crowding, the central cones have their nuclei arranged in multiple layers in a circular shape, which resembles a cake (*gateau nucleaire*).<sup>5</sup>

Cones, including their inner and outer segments, are surrounded and enveloped by the processes of müllerian glia, which concentrate on the vitreal side (*tissu clair*),<sup>5</sup> just underneath the internal limiting membrane.<sup>7</sup> Some glial cell nuclei are found in this inner layer, but most form part of the laterally displaced inner nuclear layer. Foveal development, therefore, involves the migration, elongation, concentration, and displacement of both neuronal cells and, most importantly, glial cells, the main structural element of the retina. Radiating striae found in the foveal internal limiting membrane are related to fibers of Henle but are probably mediated by glia that elaborate and are connected to the internal limiting membrane. The density of the foveal glia has been measured as 16 600–20 000 cells/ $\text{mm}^2$ .<sup>6</sup>

## FOVEOLA

The bouquet of central cones is surrounded by the foveal bottom, or foveola, which measures 350  $\mu\text{m}$  in diameter and 150  $\mu\text{m}$  in thickness (see Fig. 6.1.5). This avascular area consists of densely packed cones that are elongated and connected by the external limiting membrane. As a result of the elongation of the outer segments, the external limiting membrane is bowed vitreally, a phenomenon that has been termed *fovea*

**Fig. 6.1.7 Normal Fundus With Macula Encompassed by Major Vascular Arcades.** The macula, or central area, has the following components from center to periphery: umbo, foveola, fovea, parafovea, and perifovea.

*externa*. Both the umbo and the foveola represent the most visible part of the outer retina; however, to the level of the external limiting membrane, all cones and their axons are enveloped by the processes of Müller cells, which form the vitreal inner layer and elaborate and support the internal limiting membrane. Thus, the apex-to-apex arrangement of the optic cup is maintained by the processes of müllerian glia that face the apices of the pigment epithelial cells in the foveola. The high metabolic demands of central cones are met by direct contact with the pigment epithelium, as well as through the processes of glia, whose nuclei lie more peripheral in the inner nuclear layer and closer to the perifoveal vascular arcades (see Fig. 6.1.6).

In pathological conditions, loss of the normal foveolar reflex may indicate a glial disturbance (acute nerve cell damage, cloudy swelling) either primarily or mediated by the vitreous, which is tightly adherent to the thin internal limiting membrane. Loss of the foveal reflex may thus indicate traction or edema of glial cells and, secondarily, of cones. The inner glial layer may separate from the nuclear layer, which results in cyst-like schisis.

## FOVEA

The fovea consists of the thin bottom, a 22° declivity (the clivus),<sup>3</sup> and a thick margin (see Figs. 6.1.5–6.1.7). The bottom, or foveola, was described earlier. The declivity of 22° denotes the lateral displacement of the bipolars, horizontal and amacrine cells in the inner nuclear layer, which also includes the nuclei of its müllerian glia. The avascular foveola is surrounded by the vascular arcades, a circular system of capillaries. These

vessels are located at the level of the internal nuclear layer and leave an avascular zone of 250–600  $\mu\text{m}$  between them. The declivity also is associated with an increase in basement membrane thickness, which reaches a maximum at the foveal margin. Internal limiting membrane thickness and strength of vitreal attachment are inversely proportional; that is, adhesions are strongest in the foveola.<sup>3</sup> Not surprisingly, the foveal center is most affected in traumatic macular holes in which glial opercula suggest anterior–posterior traction as the cause. The margin of the fovea (*margo foveae*) is often seen biomicroscopically as a ring-like reflection of the internal limiting membrane, which measures 1500  $\mu\text{m}$  (disc size) in diameter and 0.55 mm in thickness (see Fig. 6.1.7).

## PARAFOVEA

The parafovea is a belt that measures 0.5 mm in width and surrounds the foveal margin (see Fig. 6.1.7). At this distance from the center, the retina features a regular architecture of layers, which includes 4–6 layers of ganglion cells and 7–11 layers of bipolar cells.<sup>8</sup>

## PERIFOVEA

The perifovea surrounds the parafovea as a belt that measures 1.5 mm wide (see Fig. 6.1.7). The region is characterized by several layers of ganglion cells and six layers of bipolar cells.<sup>8</sup>

## MACULA, OR CENTRAL AREA

The umbo, foveola, fovea, parafovea, and perifovea together constitute the macula, or central area.<sup>9</sup> The central area can be differentiated from the extra-areal periphery by the ganglion cell layer. In the macula, the ganglion cell layer is several cells thick; however, in the extra-areal periphery, it is only one-cell thick. The macular border coincides with the course of the major temporal arcades and has an approximate diameter of 5.5 mm (see Fig. 6.1.7), which comprises the diameter of the fovea (1.5 mm), twice the width of the parafovea ( $2 \times 0.5 = 1$  mm), and twice the width of the perifovea ( $2 \times 1.5 = 3$  mm).<sup>10</sup>

## EXTRA-AREAL PERIPHERY

The peripheral retina is divided arbitrarily into belts of near, middle, far, and extreme periphery.<sup>9</sup> The belt of the near periphery is 1.5 mm wide, and the belt of the middle periphery, or equator, is 3 mm wide. The far periphery extends from the equator to the ora serrata. The width of this belt varies, depending on ocular size and refractive error. The average circumference of the eye is 72 mm at the equator and 60 mm at the ora serrata, and the average width of this belt is 6 mm. Because peripheral retinal pathology is usually charted in clock hours, 1 clock hour corresponds to 5–6 mm of far peripheral circumference. Therefore, the far periphery of the retina may be divided into 12 squares that measure approximately  $6 \times 6$  mm. As a result of the insertion of the posterior vitreous base, most peripheral pathology falls into these squares. The ora serrata and pars plana are referred to as the *extreme periphery*.<sup>9</sup>

## LAYERS OF THE NEURAL RETINA

With the exception of the fovea, ora serrata, and optic disc, the neural retina is organized in layers, dictated by the direction of the müllerian glia, its structural backbone. Essentially, there is the photoreceptor layer plus the bipolar and ganglion cell layer, representing the outer first neuron and inner second and third neuron of the visual pathway. The müllerian glia elaborate the internal limiting membrane as its basement membrane and extend to the external limiting membrane, where it communicates with the apices of the RPE (Fig. 6.1.8).

The inner nuclear layer is home to the nuclei of the müllerian glia, the bipolar cells, and the horizontal and amacrine cells. The amacrine cells lie on the inside of the inner nuclear layer, and the horizontal cells lie on the outside (see Fig. 6.1.8). The inner nuclear layer has plexiform layers on either side, which connect it to the outer photoreceptor layer and the (inner) ganglion cell layer. From this simple anatomical consideration, it follows that rods and cones synapse with bipolar and horizontal cells in the outer plexiform layer. As a result of the increased length of fibers of Henle, the junctional system (the middle limiting “membrane”) is found in the inner third of the outer plexiform layer, which is the only truly plexiform portion of this layer. The bipolar cells and amacrine cells of the inner nuclear layer synapse with the dendrites of the ganglion cells in the inner

**Fig. 6.1.8 Neuronal Connections in the Retina and Participating Cells.** The inner nuclear layer contains the nuclei of the bipolar cells (second neuron) and müllerian glia. The amacrine cells are found on the inside and the horizontal cells on the outside of this layer, next to their respective plexiform connections.

plexiform layer. In embryogenesis, müllerian glia, along with their internal limiting membrane and orientation, antedate photoreceptor differentiation; this is analogous to the rest of the central nervous system, in which structural development precedes individual cell differentiation.

# Retinal Pigment Epithelium

Michael F. Marmor

## 6.2

**Definition:** A melanin-containing epithelial layer that lies between the neural retina and choroid.

### Key Features

- Absorption of scattered light.
- Control of fluid and nutrients in the subretinal space (blood–retinal barrier function).
- Visual pigment regeneration and synthesis.
- Synthesis of growth factors to modulate adjacent structures.
- Maintenance of retinal adhesion.
- Phagocytosis and digestion of photoreceptor wastes.
- Electrical homeostasis.
- Regeneration and repair for degenerative disease.

### INTRODUCTION

The retinal pigment epithelium (RPE) is a vital tissue for the maintenance of photoreceptor function.<sup>1,2</sup> It is also affected by many diseases of the retina and choroid. Embryologically, the RPE is derived from the same neural tube tissue that forms the neural retina, but the cells differentiate into a transporting epithelium, the main functions of which are to metabolically insulate and support the overlying neural retina. As a cellular monolayer, the RPE is now an attractive target for therapeutic modification and transplantation.<sup>3</sup>

### STRUCTURE AND METABOLISM

#### Cellular Architecture and Blood–Retinal Barrier

The RPE is a monolayer of interlocking hexagonal cells that are joined by tight junctions (zonulae occludens), which block the free passage of water and ions. This junctional barrier is the equivalent of the blood–retinal barrier of the neuroretina.

In the macular region, RPE cells are small (roughly 10–14  $\mu\text{m}$  in diameter), whereas toward the periphery, they become flatter and broader (diameter up to 60  $\mu\text{m}$ ). The density of photoreceptors also varies across the retina, but the number of photoreceptors that overlie each RPE cell remains roughly constant (about 45 photoreceptors per RPE cell).

In cross-section, the RPE cell is differentiated into apical and basal configurations. On the apical side (facing the photoreceptors), long microvilli reach up between (and envelop) the outer segments of the photoreceptors (Fig. 6.2.1). Melanin granules are concentrated in the apical end of the cell. The basal membrane has convoluted infolds to increase the surface area for the absorption and secretion of material. The cell structure is stabilized by a cytoskeleton of microfilaments and microtubules.

#### Pigments

The pigment that gives the RPE its name is *melanin*, found in cytoplasmic granules called *melanosomes*. In older age, melanin granules often fuse with lysosomes and break down, so the fundus in older adults typically appears less pigmented. The role of melanin in the eye remains somewhat speculative. The pigment serves to absorb stray light and minimize scatter within the eye, which has theoretical optical benefits. Visual acuity is, however, not degraded in the fundi of the very blond. Further, the appearance of the fundus can be misleading with respect to the RPE because the greatest racial differences are a result of choroidal pigmentation. Melanin also

**Fig. 6.2.1 Apical Surface of Human Retinal Pigment Epithelium as Seen Through a Scanning Electron Microscope.** Fine microvilli cover the surface and reach up between the photoreceptor outer segments (which have been peeled away in this view).

serves as a free radical stabilizer and can bind toxins and retinotoxic drugs, such as chloroquine and thioridazine, although it is unclear whether this effect is beneficial or harmful.

The other major RPE pigment is lipofuscin, which accumulates gradually with age, although it is not clear whether it is directly damaging to RPE cells as it is a component of both normal and pathological aging.

#### Metabolism and Growth Factors

A number of growth factors are elaborated by RPE cells and serve to modulate not only the behavior of the RPE but also the behavior of surrounding tissues.<sup>1,4</sup> Knowledge of these interactions is growing rapidly, and it is now recognized that the RPE is a critical part of a complex system of cellular cross-talk that controls vascular supply, permeability, growth, immunological responses, repair, and other processes vital to retinal function. Dysfunction within these systems contributes to disorders, such as age-related macular degeneration. Factors produced by the RPE include, among others, platelet-derived growth factor, which modulates cell growth and healing; pigment epithelium-derived factor, which acts as a neuroprotectant and vascular inhibitor; vascular endothelial growth factor, which can stimulate normal or pathological neovascular growth; fibroblast growth factor, which can be neurotropic; transforming growth factor, which moderates inflammation; ciliary neurotrophic factor, which supports and rescues cells; and other immune regulating components, such as Toll-like receptors and complement factors.

### MEMBRANE PROPERTIES AND FLUID TRANSPORT

#### Ion Channels and Transport Systems

The RPE membrane contains selective ion channels, and active or facilitative transport systems for ions and for metabolites, such as glucose and amino acids.<sup>5</sup> Different channels and transporters are present on the apical and basal membranes. The net effects of the asymmetrical transport systems are a movement of water across the RPE in the apical-to-basal direction and the generation of voltage across the RPE, as well as control of protein access to the subretinal space.

**Fig. 6.2.2 Mechanism of Serous Detachment.** When the retinal pigment epithelium (RPE) is normal, no serous detachment occurs beyond a focal site of leakage. When the RPE is compromised by choroidal or RPE disease that impairs outward fluid transport, a serous detachment forms until absorption across the exposed RPE balances the inward leak.

The ability of the RPE to transport water actively is very powerful, but water also moves out if the RPE barrier function is broken because of intraocular pressure and osmotic suction from the choroid. One clinical implication is that a small RPE break will not cause a serous detachment unless there is also a diffuse loss of RPE transport. Central serous chorioretinopathy involves broad dysfunction in the RPE-choroid complex (Fig. 6.2.2).<sup>6</sup>

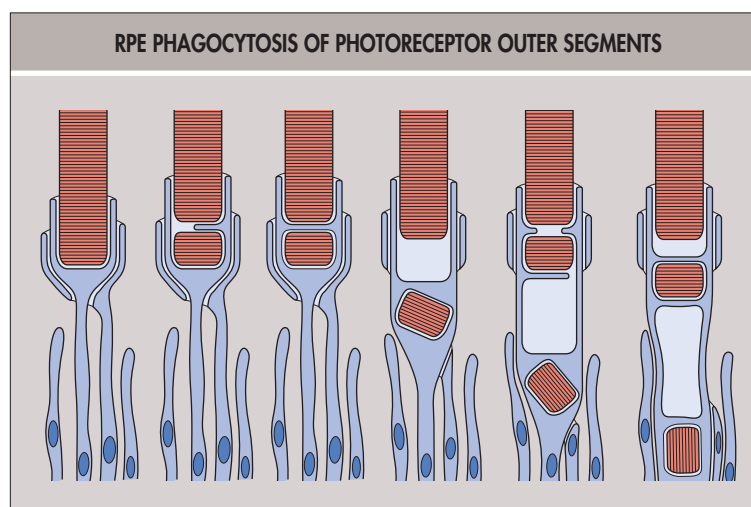

## Electrical Activity

The RPE generates no direct response to light. However, the asymmetrical transport properties of the apical and basal membranes generate a transepithelial voltage (called the *standing potential*), which can be modified secondarily by photoreceptor activity or by endogenously supplied substances.<sup>7</sup> Furthermore, light activation of photoreceptors also causes the release of a messenger substance that induces a basal RPE depolarization 5–10 minutes later. This late basal depolarization is recorded clinically as the “light response” of the clinical electrooculography (EOG). The light response is mediated through calcium-dependent chloride channels controlled, in part, by the bestrophin gene, which is altered in Best vitelliform dystrophy or autosomal recessive bestrophinopathy. The EOG is very subnormal in Best disease, but is not severely altered in most RPE disorders.<sup>7</sup>

## PHOTORECEPTOR–RETINAL PIGMENT EPITHELIUM INTERACTIONS

### Visual Pigment Regeneration

Absorption of light in the photoreceptors converts 11-*cis*-vitamin A to the all-*trans* form. This initiates transduction of light to a neural signal and begins a series of regenerative chemical changes to restore the supply of 11-*cis* vitamin A. Vitamin A is split off from the opsin molecule and carried by a transport protein to the RPE. In the RPE, vitamin A may be stored in an ester form, but eventually it is isomerized back to the 11-*cis* form by a critical enzyme RPE65, and then recombined with opsin.<sup>8</sup> Defects in several genes, including *RPE65*, *LRAT*, *RLPB* (*CRALBP*), and *RDH*, which control this regenerative cycle in the RPE, cause Leber congenital amaurosis or retinitis pigmentosa.

**Fig. 6.2.3 Retinal Pigment Epithelium (RPE) Phagocytosis of Photoreceptor Outer Segments.** The phagosome, containing the ingested material, enters the RPE cytoplasm, where it merges with lysosomes to facilitate digestion of the outdated membranes. (Adapted from Steinberg H, Wood I, Hogan MJ. Pigment epithelial ensheathment and phagocytosis of extrafoveal cones in human retina. *Philos Trans R Soc Lond* 1977;277:459–74.)

## Photoreceptor Renewal and Phagocytosis

Photoreceptors are continually exposed to radiant energy (light) and oxygen (from the choroid), which facilitates the production of free radicals that can damage membranes. Thus a process of cellular renewal is needed. Every day, upward of 100 discs at the distal end of the photoreceptors are phagocytosed by the RPE (Fig. 6.2.3), while new discs are synthesized.<sup>9</sup> The rods shed discs most vigorously in the morning at the onset of light, whereas cones shed more vigorously at the onset of darkness, and the outer segments are renewed roughly every 2 weeks. Within the RPE, the phagocytosed discs merge with lysosomes so that the material can be digested. Necessary fatty acids are recycled, whereas waste products are egested across the basal RPE membrane. Residual membrane debris, such as A2E, may contribute to the formation of lipofuscin and aging damage to the RPE.

## Retinal Adhesion and Interphotoreceptor Matrix

Adhesion of the retina to the RPE is a complex process involving several interactive mechanisms. The neural retina is pressed in place by the vitreous gel, intraocular fluid pressure, and RPE water transport, which drive or pull water through the semipermeable tissue. There is some physical resistance to separation of outer segments from enveloping RPE microvilli. The strongest mechanism for bonding the retina to the RPE space appears to be the interphotoreceptor matrix (IPM), which is an elaborate chemical structure with distinct domains that surround the rods and cones (Fig. 6.2.4A).<sup>10</sup> When neural retina is freshly peeled from the RPE, the IPM material stretches dramatically before it breaks, which shows that it is firmly attached to both neural retinal and RPE surfaces (see Fig. 6.2.4B). However, the strength of the IPM adhesive system (as well as RPE fluid transport) is constantly and acutely dependent on metabolism.<sup>11</sup> Retinal adhesive force drops to near zero within minutes after death, and adhesive strength can be reversibly restored or enhanced by tissue oxygenation.

Retinal detachment disrupts fluid transport and the IPM, and even when the retina is surgically reattached, it can take several weeks for full recovery of IPM morphology, RPE/photoreceptor intercalation and normal adhesive strength.

## REPAIR, REGENERATION, AND THERAPY

The RPE is capable of local repair (unlike the neural retina), although injured cells may migrate and take on altered characteristics. After a focal laser burn, the RPE cells that surround the burn will divide and fill the defect to form a new blood–retinal barrier within 1–2 weeks. However, large RPE defects, such as geographical atrophy, do not heal. Because growth factors from the RPE normally serve to limit excessive proliferation of cells and vasculature, RPE injury becomes a part of the cycle of pathology that stimulates vascular or fibrous growth in many retinal conditions.

**Fig. 6.2.4 Cone Sheaths of the Interphotoreceptor Matrix, Shown by Fluorescent Staining With Peanut Agglutinin.** Cone tips indent the sheaths from above; the retinal pigment epithelium (RPE) is on the bottom. (A) The matrix sheaths are short in a normal eye. (B) They stretch dramatically before breaking as the retina is peeled from the RPE. This shows that matrix material bonds across the subretinal space. (Reproduced with permission from Hageman GS, Marmor MF, Yao X-Y, Johnson LV. The interphotoreceptor matrix mediates primate retinal adhesion. *Arch Ophthalmol* 1995;113:655–60.)

The RPE monolayer, however, can be cultured and transplanted, and RPE cells can be genetically engineered or physically stimulated to modify their metabolic activity. Thus, this tissue may also have an important role in the therapy of retinal disorders, ranging from dystrophies to aging. These new options depend directly on the physical and physiological characteristics of the RPE that have been reviewed above. For example, nondamaging laser therapy (low energy or micropulses) can stimulate a release of metabolic factors, including heat shock proteins that ameliorate injury. This approach is being explored for the treatment of several diseases, including macular edema and central serous chorioretinopathy.<sup>12</sup> Cellular damage to the RPE is specifically causative of several hereditary dystrophies, including retinitis pigmentosa that involves RPE genes, such as *RPE65* and *LRAT*, and Stargardt disease in which RPE damage leads to photoreceptor death. Many groups are now investigating the use of stem cell and RPE transplantation to put normal RPE back into eyes with these diseases.<sup>3</sup> The ability to culture and modify induced pluripotent stem cells (iPSC) allows for genetic modification to create designer RPE cells prior to transplantation,<sup>13</sup> although techniques for the culturing of cells, inserting cells to reach a large area of retina, and ensuring cell survival and function over a lifetime are still evolving. Finally, trials are beginning for genetic modification of the RPE (as well as other retinal cells) within the eye through transfection with viral and other gene carriers.<sup>14</sup>

# Retinal and Choroidal Circulation

Caio Vinícius Saito Regatieri, Shiyong Roh, John J. Weiter

## 6.3

IN THIS CHAPTER  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Retinal and choroidal blood vessels are responsible for nutrition of the posterior segment. It is essential to understand the choroidal and retinal circulatory systems to better recognize and treat disease states of the posterior segment.

### Key Features

- Retinal vascular anatomy.
- Choroidal vascular anatomy.
- Inner and outer blood–retinal barriers.
- Choroidal and retinal blood flow measurements.

## INTRODUCTION

Because many of the important diseases of the posterior segment are caused by changes in the vasculature of the retina and choroid, it is important to understand the circulatory systems involved to better recognize and treat disease states of the posterior segment. In this chapter, the anatomy and physiology of these circulatory systems are discussed.

## POSTERIOR SEGMENT VASCULAR ANATOMY

### Retinal Vascular Anatomy

The retinal blood vessels provide nourishment for the inner two thirds of the retina. The central retinal artery, which is the first branch of the ophthalmic artery, is an end artery that has no significant anastomoses.<sup>1</sup> In the area of the lamina cribrosa, its lumen measures about 170  $\mu\text{m}$  in diameter. Typically, just before its exit from the optic nerve, the central retinal artery divides into the superior and inferior papillary arteries, which, in turn, divide into nasal and temporal quadratic branches (Fig. 6.3.1A). The anatomic division of the retinal arteries into superior and inferior halves is usually maintained throughout the retina because normal retinal vessels rarely cross the horizontal raphe (see Fig. 6.3.1A). Cilioretinal arteries, derived from the posterior ciliary arteries, are variably present and emanate from the temporal rim of the optic nerve head toward the macula (see Fig. 6.3.1A).

Arteries and veins remain in the nerve fiber layer. Throughout the retina, the capillaries are arranged in laminar meshworks.<sup>2</sup> Depending on the thickness of the retina, the capillary meshwork can vary from three layers at the posterior pole to one layer in the periphery. The arterial intra-retinal branches supply three layers of capillary networks:

- The radial peripapillary capillaries.
- Superficial capillaries in the ganglion cell and nerve fiber layers.
- Deep, denser, capillaries in the inner nuclear layer.

Optical coherence tomography angiography (OCTA) reveals the microvasculature and the blood flow in the retinal capillaries in a noninvasive manner. Automated segmentation of the full-thickness retinal OCTA scans show in vivo the “superficial” and “deep” retinal vascular plexuses, and choriocapillaris. The superficial plexus shows a continuous and linear shape with a homogeneous wall. The vessels are evenly distributed and resemble a spider’s web. The deep network in healthy eyes has a regular distribution around the foveal avascular zone (FAZ), with more complex minute interconnections.

Like capillary networks elsewhere in the body, the retinal capillaries assume a meshwork configuration to ensure adequate perfusion to all inner retinal cells (see Fig. 6.3.1C).

A capillary-free zone is present around each of the larger retinal arteries and veins, but it is more prominent around arteries, where it measures up to 100  $\mu\text{m}$  in diameter. In the fovea and the far retinal periphery, retinal capillaries are absent. The FAZ is 400–500  $\mu\text{m}$  in diameter in normal eyes.

The venous drainage of the retina generally follows the arterial supply. Retinal veins (mainly venules) are present in the inner retina, where they occasionally interdigitate with their associated arteries. When two vessels cross, the artery usually lies anterior to the vein, and the two vessels share a common adventitial coat. Many more arteriovenous crossings occur temporally than nasally because the nasal vessels assume a much straighter course. The crossings are important because they represent the most common site of branch retinal vein obstructions. The retinal veins drain into the central retinal vein, which also acts as the major efferent channel for the vessels of the optic nerve (see Fig. 6.3.1A).<sup>2</sup>

### Choroidal Vascular Anatomy

The choroid is, by far, the most vascular portion of the eye and, by weight, one of the most vascular tissues in the body. The choroid is responsible for the vascular support of the outer retina (see Fig. 6.3.1B). A structurally and functionally normal choroidal vasculature is essential for retinal function: Abnormal choroidal blood volume and/or compromised flow can result in photoreceptor and retinal pigment epithelium (RPE) dysfunction and death.<sup>3</sup> Other likely functions include light absorption, thermoregulation via heat dissipation, and modulation of intraocular pressure (IOP) via vasomotor control of blood flow. The choroid also plays an important role in the drainage of the aqueous humor from the anterior chamber via the uveoscleral pathway.

The blood supply to the choroid is from branches of the anterior and posterior ciliary arteries, branches of the ophthalmic artery. The overall structure of the choroid is segmental; this segmental distribution of blood begins at the level of the posterior ciliary branches and is mirrored in the vortex drainage system. As a result of the segmental distribution, the large and medium-sized choroidal arteries act as end arteries.

Histologically, starting from the retinal (inner) side, the choroid is divided into five layers:

- Bruch’s membrane.
- Choriocapillaris (layer of capillaries).
- Sattler’s layer (layer of medium diameter blood vessels).
- Haller’s layer (layer of large diameter blood vessels).
- Suprachoroida (transitional zone between choroid and sclera).<sup>4</sup>

The choriocapillaris is a highly anastomosed network of capillaries, forming a thin sheet apposed to Bruch’s membrane. The fibrous basement membrane of the capillary endothelial cells forms the outermost layer of Bruch’s membrane in humans. The choriocapillaris is about 10  $\mu\text{m}$  thick at the fovea, where there is the greatest density of capillaries, thinning to about 7  $\mu\text{m}$  in the periphery. The capillaries arise from the arterioles in Sattler’s layer, each of which gives rise to a hexagonal (or lobular) shaped domain of a single layer of capillaries, giving a patch-like structure to the choriocapillaris. The choriocapillaris has large diameter capillaries of 20–25  $\mu\text{m}$ , which allow the passage of multiple red blood cells at any moment in time. Unlike the retinal capillaries, the choriocapillaris has

**Fig. 6.3.1 Angiogram From Scanning Laser Ophthalmoscopy.** (A) Normal fluorescein angiogram shows the normal filling of retinal arteries and veins; note the cilioretinal artery (*green arrow*). (B) Normal indocyanine green angiogram shows the normal filling of choroidal vessels. (C) Magnified area from image A shows the retinal capillaries (*green arrows*) close to the foveal avascular zone. (D) Indocyanine green angiogram shows a choroidal neovascularization (*green arrow*) secondary to age-related macular degeneration (AMD).

fenestrations of 700–800 nm diameter, which allows more rapid transport of molecules (leakage).<sup>4</sup>

Besides the choriocapillaris, the choroid presents two other vascular regions: the outer Haller's layer of large blood vessels and the inner Sattler's layer of medium and small arteries and arterioles that feed the capillary network, and veins. The stroma (extravascular tissue) contains collagen and elastic fibers, fibroblasts, nonvascular smooth muscle cells, and numerous very large melanocytes that are closely apposed to the blood vessels. As in other types of connective tissue, there are numerous mast cells, macrophages, and lymphocytes.

### BLOOD–RETINAL BARRIER

The blood–retinal barrier (BRB) controls the exchange of metabolites and waste products between the vascular lumen and the neural retina and is

formed by the interaction of retinal glia and pericytes with the retinal vascular endothelium cells. In addition to the vascular contribution, the retina also possesses an epithelial barrier, the RPE, which controls the flow of fluid and nutrients from the highly vascularized choroid into the outer retina. Together, the vascular and epithelial components of the BRB maintain the specialized environment of the neural retina. Both the vascular endothelium (inner barrier) and the RPE (outer barrier) possess well-developed junctional complexes that include adherens and tight junctions.

The inner BRB controls permeability from the retinal blood vessels and consists of a well-developed junctional complex (adherens and tight junctions) in the vascular endothelial cells as well as no fenestration. The tight junctions restrict flux of a wide variety of substances, such as lipids and protein. The retinal capillaries are relatively impermeable, even to particles as small as sodium ions. The adherens junctions are essential to development of the barrier and influence the formation of the tight junction.

Together, the adherens junctions and tight junctions create the resistance barrier to the neural parenchyma. Although it is at the endothelium of the retinal capillaries that the barrier resides, the glial cells may play a role as metabolic intermediaries between the retinal capillaries and retinal neurons.<sup>5</sup> Thus, macromolecules and ions do not passively diffuse into the retina from the circulation but are associated with selective active transport into the retina.

The outer BRB is formed by tight junctions between cells of the RPE. The RPE resting on the underlying Bruch's membrane separates the neural retina from the fenestrated choriocapillaris and plays an important role in transporting nutrients from the blood to the outer retina. Although inter-RPE cell tight junctions are important in the control of paracellular movement of fluids and molecules between the choroid and retina, the polarized distribution of membrane proteins in the RPE is also important. The RPE plays an active role in supplying glucose to the photoreceptors and also retinol that is required for visual pigment synthesis.<sup>6</sup> The receptors that exist on the basal and lateral cell membranes of the RPE for nutrients have to be transported to the outer retina.

Although the retina is protected by the inner (retinal vascular endothelium cells) and outer (RPE) BRBs, *in vivo*, some leakage probably occurs. Most likely, this protein leakage is actively transported across the RPE into the choroid and/or removed through Schlemm's canal. Choroidal proteins exit the eye through emissary canals (openings in the sclera for vessels and nerves) or through the sclera, probably facilitated by the relatively high tissue pressure of the eye (IOP).<sup>6</sup>

In many clinically important pathological conditions, including diabetic retinopathy, retinal vein occlusion, and some inflammatory diseases, there is a breakdown of the inner BRB, leading to leakage of blood components to the neural retina. In addition, outer BRB breakdown can occur in conditions such as age-related macular degeneration (AMD) (see Fig. 6.3.1D), central serous chorioretinopathy, accelerated hypertension, and toxemia of pregnancy. Breakdown of the outer BRB results in serous retinal detachment or RPE detachment.

## RETINAL AND CHOROIDAL BLOOD FLOW

There are several techniques to analyze both qualitatively and quantitatively the retinal and choroidal blood flow, such as the following:

- Fluorescein angiogram with dye dilution (Video 6.3.1).
- Indocyanine green with dye dilution.
- Optical coherence tomography angiography.
- Laser Doppler velocimetry.
- Laser Doppler flowmetry.
- Scanning laser flowmetry.
- Color Doppler ultrasonography (Fig. 6.3.2).

These techniques have greatly enhanced the ability to quantify ocular perfusion defects in many disorders, including glaucoma, AMD, diabetic retinopathy and vascular occlusions, which are major causes of blindness in the developed world. However, methods for accurate, reproducible measurement of retinal and choroidal blood flow are still being perfected because of the difficult access to the retinal and choroidal circulation.

Quantitative retinal blood flow is studied mainly by the use of laser Doppler flowmetry and laser Doppler velocimetry, which are noninvasive techniques which permit the assessment of relative blood velocity, volume, and flow within a sampled volume of tissue. Using these techniques, it has been shown that the total retinal blood flow in healthy subjects is  $44.0 \pm 13.3 \mu\text{L}/\text{min}$ . The blood flow is highest in the temporal inferior quadrant, followed by that in the temporal superior quadrant, the nasal inferior quadrant, and the nasal superior quadrant. In all quadrants retinal blood velocities are linearly correlated to vessel diameters.<sup>7</sup>

Scanning laser ophthalmoscopic fluorescein angiography has also provided important information on retinal hemodynamics in normal individuals and those with glaucoma. In healthy individuals, arteriovenous passage times measured by scanning laser ophthalmoscopic angiography has been reported as averaging  $1.58 \pm 0.4$  seconds and mean dye velocity averaging  $6.67 \pm 1.59 \text{ mm}/\text{sec}$  in a large study of 221 individuals. In the same study, capillary flow velocity averaged  $2.89 \pm 0.41 \text{ mm}/\text{sec}$  in healthy subjects.<sup>8</sup> In patients with primary open-angle glaucoma, there is an 11% reduction in the mean dye velocity within the major retinal arteries. It has also been noted that arteriovenous passage time within retina is 41% slower in primary open-angle glaucoma.<sup>9</sup> Several studies have shown that patients with glaucoma suffer from inadequate ocular blood flow and that a relationship exists between ocular hemodynamics and progression of the disease.

**Fig. 6.3.2 Color Doppler Image of the Ophthalmic Artery.** The Doppler-shifted spectrum (time-velocity curve) is displayed at the bottom of the image. Red pixels represent blood movement toward to the transducer.

Unlike retinal arteries, retinal veins show no pulsations in blood velocity except at the point of exit from the globe.<sup>10</sup> The venous pressure of the intraocular veins exiting the eye depends on IOP and coincides with the pulse, which results in a pulsating venous perfusion pressure. The retinal venous outflow resistance is located mainly at the lamina cribrosa. The closed nature of the eye means that the pulsatile choroidal arterial inflow results in a pulse-related change in IOP, which causes a venous pulse. Depending on the relationship between IOP and venous pressure, this may result in a clinically visible pulse of the veins at their point of exit from the globe.

The choroid is primarily a vascular structure supplying the outer retina. The choroid circulation exhibits one of the highest rates of blood flow in the body. In fact, per tissue gram, the choroid has four times more blood flowing through it than does through the cortex of the kidney. Several studies showed that the choroid receives 65%–85% and the retina 5% or less of the ocular blood flow.

Using laser Doppler velocimetry, the choroidal blood flow is documented to be  $800 \mu\text{L}/\text{min}$ , 18 times higher than retinal blood flow. With advancing age, the choroidal blood velocity and choroidal thickness decrease significantly, and this may be related to the pathogenesis of AMD. Interestingly, mean blood pressure, smoking, and gender have no influence on choroidal blood flow parameters.

Studies assessing the choroidal circulation indicate a significant reduction of choroidal blood flow and volume in patients with glaucoma, AMD, and nonproliferative and proliferative diabetic retinopathy.

The major differences of the retinal and choroidal circulatory systems are shown in Table 6.3.1.

## RETINA AND CHOROIDAL CIRCULATION EVALUATED BY OCTA

Fluorescein angiography and indocyanine green angiography have been the gold standard modalities for the evaluation of retinal and choroidal vasculature in the last three decades. The advantage of these imaging modalities lies in their ability to document retinal and choroidal vasculature through the dynamic assessment of contrast transit over time in the intravascular and extravascular spaces. However, their disadvantages include the absence of depth resolution, blurring of details by contrast leakage, and the inability to selectively evaluate different levels of the retinal and choroidal microvasculature. In addition, these angiographic methods require the use of intravenous dye, which may cause adverse reactions, such as nausea, vomiting, and, rarely, anaphylaxis.<sup>11</sup>

OCTA is a noninvasive imaging technique, which, in contrast to dye-based angiography, is faster and depth-resolved, allowing the evaluation of the vascular plexuses of the retina and choroid.<sup>12</sup> The OCTA software offers the option of  $2 \times 2 \text{ mm}$ ,  $3 \times 3 \text{ mm}$ ,  $6 \times 6 \text{ mm}$ , and  $8 \times 8 \text{ mm}$  OCTA images and automated segmentation of these full-thickness retinal scans into the “superficial” and “deep” inner retinal vascular plexuses,

**TABLE 6.3.1 Major Differences Between the Retinal and Choroidal Circulatory Systems**

Property	Retinal Circulation	Choroidal Circulation
Supply	Central retinal artery	Ciliary arteries
Blood flow	Normal for tissue	Highest in body
Tissue nourishment	Inner two thirds of retina	Outer one third of retina (photoreceptor and retinal pigment epithelium [RPE] complex)
Cellular junctions	Tight junctions between endothelial cells	Fenestrations in choriocapillaris
Nature of vasculature	End artery system	Functionally end artery system (lobular-shaped domain)
Blood flow regulation	Autoregulation	Controlled by the autonomic nervous system

outer retina, and choriocapillaris (Fig. 6.3.3). The OCTA segmentation of the superficial inner retina contains a projection of the vasculature in the retinal nerve fiber layer and the ganglion cell layer. The deep inner retina OCTA segmentation shows a composite of the vascular plexuses at the border of the inner plexiform layer (IPL) and inner nuclear layer (INL) and the border of the INL and outer plexiform layer.<sup>12</sup>

Published studies suggest that OCTA is efficacious in the evaluation of common ophthalmological diseases, such as age-related macular degeneration (AMD), diabetic retinopathy, occlusions of arteries and veins, and glaucoma. OCTA can detect changes in choroidal blood vessel flow and can elucidate the presence of choroidal neovascularization in a variety of conditions, especially in AMD.<sup>12</sup> It provides a highly detailed view of the retinal vasculature, which allows for accurate delineation of the FAZ in diabetic eyes and detection of subtle microvascular abnormalities in diabetic and vascular occlusive eyes (Fig. 6.3.4). OCTA is now proven to be an effective noninvasive tool to evaluate the retina and choroid circulation.

## REGULATION OF RETINAL AND CHOROIDAL BLOOD FLOWS

Regulation of blood flow through the choroid, as in the body in general, is under the control of the autonomic nervous system. Stimulation of the cervical sympathetic chain decreases choroidal flow, and sympathectomy increases it.<sup>13</sup> The choroid does not show evidence of autoregulation, the lack of which may have serious consequences. Changes in IOP are not reflected by compensatory changes in choroidal vascular pressure,<sup>13</sup> and sudden changes in IOP, as occur in the opening of the eye during surgery, can induce uveal effusion.

Because the autonomic tonus probably protects the eye from transient elevations in the systemic blood pressure under normal circumstances, if the nervous regulation breaks down in the presence of systemic hypertension, fluid may be forced through the retinal pigment epithelial barrier into the retina.<sup>14</sup> Such changes could contribute to the pathology of central serous chorioretinopathy, cystoid macular edema, and hypotony maculopathy. The ophthalmic artery and its branches are innervated richly with adrenergic fibers until the lamina cribrosa is reached.

From that point on, no nervous system control of the retinal circulation occurs.<sup>15</sup> The retinal circulation must therefore depend on local autoregulation to maintain a constant metabolic environment. The process of autoregulation in a vascular bed maintains constant or nearly constant blood flow through a wide range of perfusion pressures. Autoregulation of the retina is commonly used today in a much broader sense, to encompass the local homeostatic blood flow mechanisms that provide a constant metabolic environment in the retina despite various conditions that tend to upset this equilibrium. Blood flow in the retina appears to be primarily controlled by metabolic needs, especially the need for oxygen<sup>16</sup>; the accumulation of metabolic byproducts, such as carbon dioxide; and changes in pH. It is necessary to understand the factors that can influence autoregulation of the retinal circulation because these may have important clinical implications.<sup>17</sup>

# Vitreous Anatomy and Pathology

J. Sebag

6.4

**Definition:** Vitreous is an extended extracellular matrix situated between the lens and the retina, approximately 4 mL in volume and 16.5 mm in emmetropic axial length.

## Key Features

- Optically clear.
- May modulate growth of the eye.
- Maintains media transparency.
- Serves as a reservoir for antioxidants.
- Plays a role in oxygen physiology of the eye.
- Separates from the retina during aging, in most cases resulting in innocuous posterior vitreous detachment (PVD).
- Anomalous PVD is a unifying concept in various vitreoretinopathies, including vitreo-maculopathies and rhegmatogenous retinal detachment.

## Associated Features

- PVD is a common cause of vitreous floaters and may degrade contrast sensitivity function, known as Vision Degrading Myodesopsia.
- Some surgeons advocate vitrectomy for symptomatic vitreous floaters to normalize contrast sensitivity function.
- PVD and vitrectomy increase oxygen levels contributing to cataractogenesis.
- Anomalous PVD is the inciting event in diseases of the vitreous-macular interface via vitreomacular traction and vitreoschisis and contributes to proliferative diabetic retinopathy, macular edema in diabetes and vein occlusions, and possibly exudative age-related macular degeneration.

## INTRODUCTION

Although vitreous is the largest structure within the eye, constituting 80% of the ocular volume, investigators of vitreous anatomy are hampered by two fundamental difficulties:

- Attempts to characterize vitreous morphology are efforts to visualize a tissue that is invisible “by design” (Fig. 6.4.1).
- The various techniques that were previously employed to study vitreous structure were flawed by artifacts induced by tissue fixatives, which caused precipitation of hyaluronan, formerly called *hyaluronic acid*.

The development of slit-lamp biomicroscopy by Gullstrand in 1911 was expected to enable clinical investigation of vitreous structure without the introduction of these artifacts. Nonetheless, a widely varied set of descriptions resulted. This phenomenon even persists in more modern investigations. Consider that in the 1970s, Eisner<sup>1</sup> described “membranelles” and Worst<sup>2</sup> described “cisterns”; in the 1980s, Sebag and Balazs<sup>3,4</sup> identified “fibers”; and in the 1990s, Japanese investigators<sup>5</sup> described “pockets” in the posterior vitreous,<sup>5,6</sup> although the largest one is very likely the same as Worst’s bursa premacularis.<sup>2</sup> What has been largely agreed upon is the molecular composition of vitreous.<sup>4,7–11</sup>

## MOLECULAR MORPHOLOGY

### Supramolecular Organization

Vitreous is composed of a dilute meshwork of collagen fibrils (Fig. 6.4.2) interspersed with extensive arrays of hyaluronan molecules.<sup>7–9</sup> The collagen

**Fig. 6.4.1 Vitreous Obtained at Autopsy on a 9-Month-Old Child.** The sclera, choroid, and retina were dissected off the transparent vitreous, which remained attached to the ora serrata. This was a neural retina that was firmly adherent to the vitreous base and could not be dissected. The vitreous was almost entirely gel (because of the young age of the donor) and thus was solid and maintained its shape, although situated on a surgical towel exposed to room air. (Courtesy The New England Eye Bank, Boston, MA.)

**Fig. 6.4.2 Structure of Human Vitreous Collagen Fibril.** Schematic diagram of the major heterotypic collagen fibrils of vitreous based on current knowledge of the structure and biophysical attributes of the constituent molecules. (With permission from Bishop P. The biochemical structure of mammalian vitreous. Eye 1996;10:64.)

fibrils provide a solid structure that is “inflated” by the hydrophilic hyaluronan.<sup>10</sup> Rheological observations also suggest the existence of an important interaction between hyaluronan and collagen.<sup>12</sup> Balazs hypothesized that the hydroxylysine amino acids of collagen mediate polysaccharide binding to the collagen chain through O-glycosidic linkages.<sup>10</sup> These polar amino acids are present in clusters along the collagen molecule, consistent with proteoglycans attachment to collagen in a periodic pattern.<sup>13</sup>

Hyaluronan–collagen interaction in the vitreous body may be mediated by a third molecule. In cartilage, “link glycoproteins” have been identified that interact with proteoglycans and hyaluronan.<sup>14</sup> Supramolecular complexes of these glycoproteins are believed to occupy interfibrillar spaces. Bishop<sup>8</sup> has elegantly described the potential roles of type IX collagen chondroitin sulfate chains, hyaluronan, and opticin in the short-range spacing of collagen fibrils and how these mechanisms might break down in aging and disease.

Many investigators believed that hyaluronan–collagen interaction occurs on a “physicochemical” rather than a “chemical” level.<sup>15</sup> Reversible complexes of an electrostatic nature between solubilized collagen and various glycosaminoglycans could, indeed, form because electrostatic binding between the negatively charged hyaluronan and the positively charged collagen likely occurs in vitreous.

## VITREOUS ANATOMY

### Macroscopic Morphology

In an emmetropic adult human eye, vitreous is approximately 16.5 mm in axial length with a depression anteriorly just behind the lens (patellar fossa). The hyloideocapsular ligament of Weiger is the annular region (1–2 mm in width and 8–9 mm in diameter), where vitreous is attached to the posterior aspect of the lens. Erggelet's or Berger's space is at the center of the hyaloid capsular ligament. The canal of Cloquet arises from this space and courses posteriorly through the central vitreous (Fig. 6.4.3), which is the former site of the hyaloid artery in the embryonic vitreous.<sup>16</sup> The former lumen of the artery is an area devoid of collagen fibrils and surrounded by multifenestrated sheaths that were previously the basal

laminae of the hyaloid artery wall.<sup>4</sup> Posteriorly, Cloquet's canal opens into a funnel-shaped region anterior to the optic disc, known as the *area of Martegiani*.

Within the adult human vitreous there are parallel nonbranching fibers that course in an anteroposterior direction (Fig. 6.4.4), arising from the vitreous base, where they insert anterior and posterior to the ora serrata. The connections between the peripheral anterior vitreous fibers and the retina underlie the pathophysiology of retinal tears because of the strong adhesion in this location.<sup>4</sup> The peripheral vitreous fibers are circumferential with the vitreous cortex, whereas the central fibers “undulate” parallel to Cloquet's canal. Ultrastructural studies have demonstrated that collagen, organized in bundles of parallel fibrils, is the only microscopic structure corresponding to these fibers.<sup>3</sup> It is hypothesized that visible vitreous fibers form when hyaluronan molecules no longer separate the microscopic collagen fibrils, which results in the aggregation of collagen fibrils into bundles from which hyaluronan molecules are excluded.<sup>3,4,17</sup> The areas adjacent to these large fibers have a low density of collagen fibrils and a relatively high concentration of hyaluronan molecules. Composed primarily of “liquid vitreous,” these areas scatter very little incident light and, when prominent, constitute the “lacunae” seen with aging (Fig. 6.4.5).

**Fig. 6.4.3** Vitreous anatomy according to classic anatomical and histological studies. (Reprinted with permission from Schepens CL, Neetens A, editors. The vitreous and vitreo-retinal interface. New York: Springer-Verlag; 1987:20.)

**Fig. 6.4.4** The Eye of a 57-Year-Old Man After Dissection of the Sclera, Choroid, and Retina, With the Vitreous Still Attached to the Anterior Segment. The specimen was illuminated with a slit-lamp beam shone from the side, and the view here is at a 90° angle to this plane to maximize the Tyndall effect. The anterior segment is below and the posterior pole is at the top of the photograph. Bundles of prominent fibers course anteroposteriorly to exit via the premacular dehiscence in the vitreous cortex.

**Fig. 6.4.5** Human Vitreous in Old Age. The central vitreous has thickened, tortuous fibers. The peripheral vitreous has regions devoid of any structure, which contain liquid vitreous. These regions correspond to “lacunae,” as seen clinically using biomicroscopy (arrows).

**Fig. 6.4.6 Fundus View of Posterior Vitreous Detachment.** (A) The posterior vitreous in the left eye of this patient is detached, and the prepapillary hole in the posterior vitreous cortex is anterior to the optic disc (*arrows, slightly below and to the left of the optic disc here*). (B) A slit beam illuminates the retina and optic disc (*at bottom*) in the center. To the right is the detached vitreous. The posterior vitreous cortex is the dense, whitish gray, vertically oriented linear structure to the right of the slit beam. (Courtesy C. L. Trempe, MD.)

## Microscopic Morphology

The vitreous cortex is the peripheral “shell” of the vitreous body that courses forward and inward from the anterior vitreous base (anterior vitreous cortex) and posteriorly from the posterior border of the vitreous base, (posterior vitreous cortex). The posterior vitreous cortex is 100–110  $\mu\text{m}$  thick and consists of densely packed collagen fibrils.<sup>4,18</sup> Although no direct connections exist between the posterior vitreous and the retina, the posterior vitreous cortex is adherent to the inner limiting membrane (ILM) of the retina, which is, in part, the basal lamina of retinal Müller cells. Adhesion between the posterior vitreous cortex and the ILM probably results from the action of various extracellular matrix molecules.<sup>19</sup>

A hole in the prepapillary vitreous cortex can sometimes be visualized clinically when the posterior vitreous is detached from the retina (Fig. 6.4.6). If peripapillary tissue is torn away during PVD and remains attached to the vitreous cortex about the prepapillary hole, it is referred to as Weiss’ ring. Vitreous can extrude through the prepapillary hole in the vitreous cortex but does so to a lesser extent than through the premacular vitreous cortex, where, occasionally, vitreomacular adhesion and axial traction can cause vitreomacular traction syndrome.<sup>20</sup> Tangential vitreomacular traction<sup>21</sup> is implicated in the pathogenesis of macular holes and macular pucker,<sup>22</sup> often with vitreoschisis (see below).

Embedded within the posterior vitreous cortex are hyalocytes. These mononuclear phagocytes are spread widely apart in a single layer situated 20–50  $\mu\text{m}$  from the ILM of the retina. The highest density of hyalocytes is in the vitreous base, followed next by the posterior pole, with the lowest density at the equator. Hyalocytes are oval or spindle shaped, 10–15  $\mu\text{m}$  in

**Fig. 6.4.7 Ultrastructure of Human Hyalocyte.** A mononuclear cell is embedded within the dense collagen fibril (CF) network of the vitreous cortex. There is a lobulated nucleus (N) with a dense marginal chromatin (C). In the cytoplasm, there are mitochondria (M), dense granules (*arrows*), vacuoles (V), and microvilli (MI). (Courtesy Joe Craft and D. M. Albert, MD.)

diameter, and contain a lobulated nucleus, a well-developed Golgi complex, smooth and rough endoplasmic reticula, many large lysosomal granules (periodic acid–Schiff positive), and phagosomes (Fig. 6.4.7). Balazs<sup>10</sup> pointed out that hyalocytes are located in the region of highest hyaluronan concentration and suggested that these cells are responsible for hyaluronan synthesis. Hyalocyte capacity to synthesize collagen was first demonstrated by Newsome et al.<sup>23</sup> Similar to chondrocyte metabolism in the joint, hyalocytes may synthesize vitreous collagen at some, but not all, times during life. The phagocytic capacity of hyalocytes is consistent with the presence of pinocytotic vesicles and phagosomes and the presence of surface receptors that bind immunoglobulin G and complement.<sup>18</sup> It is intriguing to consider that hyalocytes are among the first cells to be exposed to any migratory or mitogenic stimuli during various disease states, particularly proliferative vitreoretinopathy. These cells may, therefore, be important in the pathophysiology of proliferative disorders at the vitreous–retinal interface, including macular pucker.<sup>24</sup>

The vitreo–retinal interface is not only important as the site of many tractional and proliferative vitreoretinal disorders<sup>25</sup> but also impacts therapeutics. Pharmacologic vitreolysis of vitreoretinal adhesion<sup>26–28</sup> as well as drug delivery to the macula<sup>29</sup> and transretinal gene therapies via viral vectors that must traverse this interface are influenced by the underlying anatomy and biochemistry of the vitreous–retinal interface.<sup>30</sup> The basal laminae surrounding the vitreous body are composed of type IV collagen closely associated with glycoproteins.<sup>18,30</sup>

At the pars plana, the basal lamina has a true lamina densa. The basal lamina posterior to the ora serrata is the ILM of the retina. The layer immediately adjacent to the Müller cell is a lamina rara, which is 0.03–0.06  $\mu\text{m}$  thick. The lamina densa is thinnest at the fovea (0.01–0.02  $\mu\text{m}$ ) and disc (0.07–0.1  $\mu\text{m}$ ). It is thicker elsewhere in the posterior pole (0.5–3.2  $\mu\text{m}$ )

than at the equator or vitreous base.<sup>4,18</sup> The anterior surface (vitreous side) of the ILM is normally smooth, whereas the posterior aspect is irregular, filling the spaces created by the irregular subjacent nerve fiber layer. This feature is most marked at the posterior pole, whereas in the periphery both the anterior and posterior aspects of the ILM are smooth. The significance of this topographical variation is not known. At the rim of the optic disc the ILM ceases, although the basal lamina continues as the “inner limiting membrane of Elschnig.”<sup>31</sup> This membrane is 50 microns thick and is believed to be the basal lamina of the astroglia in the papilla. At the central-most portion of the optic disc, the membrane thins to 20 microns, follows the irregularities of the underlying cells of the optic nerve head, and is composed only of glycosaminoglycans with no collagen.<sup>31</sup> This structure is known as the *central meniscus of Kuhnt*. The thinness and chemical composition of these membranes may account for, among other phenomena, the frequency with which abnormal cell proliferation arises from or near the optic disc in proliferative diabetic retinopathy and macular pucker.

The vitreous body is most firmly attached at the vitreous base, disc, and macula and over retinal blood vessels. The posterior aspect (retinal side) of the ILM demonstrates irregular thickening farther posteriorly from the ora serrata.<sup>4,18,30</sup> So-called attachment plaques between the Müller cells and the ILM have been described in the basal and equatorial regions of the fundus but not in the posterior pole, except for the fovea.<sup>4,18,30</sup> It has been hypothesized that these develop in response to vitreous traction on the retina. The thick ILM in the posterior pole dampens the effects of this traction, except at the fovea, where the ILM is thin. The thinness of the ILM and the purported presence of attachment plaques at the central macula could explain the predisposition of this region to changes induced by traction. An unusual vitreous–retinal interface overlies retinal blood vessels. Physiologically, this may provide a shock-absorbing function to dampen arteriolar pulsations. However, pathologically, this arrangement could also account for the proliferative and hemorrhagic events that are associated with vitreous traction on retinal blood vessels.

## AGE-RELATED CHANGES

### Embryology and Postnatal Development

Early in embryogenesis, the vitreous is filled with blood vessels, called the *vasa hyaloidea propria*. It is not known what stimulates regression of this hyaloid vascular system, but recent studies have identified significant changes in the proteome of the human embryo that may underlie the process of vascular regression.<sup>31</sup> Teleologically, this seems necessary not only to induce regression of the vascular primary vitreous but also to inhibit subsequent cell migration and proliferation and thereby minimize light scatter and achieve transparency. Identifying the phenomena inherent in this transformation may reveal how to control pathological neovascularization in the eye and elsewhere. Recent studies<sup>32</sup> have characterized the proteomic profile of embryonic human vitreous during hyaloid vessel regression in an attempt to identify the factors that might create and maintain a clear vitreous. These studies found that there is upregulation of certain pathways with concurrent downregulation of others. These findings may, thus, have relevance to developing new therapeutic strategies to induce the regression of pathological neovascularization in ocular and systemic diseases, such as metastatic carcinoma.

### Developmental Anomalies

Persistent fetal vasculature (PFV) syndrome is an uncommon developmental anomaly in which the hyaloid vasculature of the primary vitreous fails to involute. This condition was initially described in detail by Reese<sup>33</sup> in his 1955 Jackson Memorial Lecture, where he named it *persistent hyperplastic primary vitreous*. The subject was revisited by Goldberg<sup>34</sup> in his 1997 Jackson Memorial Lecture, where he coined the term *PFV*.

There is a spectrum of PFV severity, ranging from pupillary strands and a Mittendorf's dot to a dense retrolenticular membrane and/or retinal detachment. Anterior PFV consists of retrolenticular fibrovascular tissue that attaches to the ciliary processes and draws them centrally, inducing cataract formation, shallowing of the anterior chamber, and angle-closure glaucoma. Iris vessel engorgement and recurrent intraocular hemorrhage can result in phthisis bulbi, although the prognosis with surgery is often fair.<sup>35</sup> Posterior PFV consists of a prominent vitreous fibrovascular stalk that emanates from the optic nerve and courses anteriorly. Preretinal membranes at the base of the stalk are common, often with tractional retinal folds and traction retinal detachment. The prognosis for posterior PFV is poor, suggesting that pharmacotherapy may be the only solution for

this form of PFV. In this regard, it has recently been proposed that insufficient levels of vitreous endostatin may be important in the pathogenesis of PFV,<sup>36</sup> consistent with the aforementioned proteomic studies.<sup>32</sup>

Improper vitreous biosynthesis during embryogenesis underlies a variety of developmental abnormalities.<sup>37</sup> Normal vitreous biosynthesis requires normal retinal development because at least some of the vitreous structural components are synthesized by retinal Müller cells.<sup>23</sup> A clear gel, typical of normal “secondary vitreous,” appears only over developed retina. Thus in various developmental anomalies, such as retinopathy of prematurity (ROP), familial exudative vitreoretinopathy, and related entities, vitreous that overlies undeveloped retina in the peripheral fundus is a viscous liquid but not a gel.<sup>37</sup> The extent of this finding depends, at least in ROP, on the gestational age at birth because the younger the individual, the more undeveloped is the peripheral retina, especially temporally. In other truly congenital conditions, there are inborn errors of collagen metabolism that have now been elucidated. In Stickler's syndrome, defects in specific genes have been associated with particular phenotypes, thus enabling the classification of patients with Stickler's syndrome into four subgroups.<sup>38</sup> Patients in the subgroups with vitreous abnormalities are found to have defects in the genes coding for type II procollagen and type V/XI procollagen.

Ongoing synthesis of both collagen and hyaluronan occurs during development to adulthood,<sup>4</sup> and hyaluronan stabilizes the collagen network.<sup>10,11</sup>

### Aging of the Vitreous Body

Substantial rheological, biochemical, and structural alterations occur in vitreous during aging.<sup>39–41</sup> After age 45–50 years, there is a significant decrease in the gel volume and an increase in the liquid volume of human vitreous. These findings were confirmed qualitatively in postmortem studies of dissected human vitreous, and liquefaction was observed to begin in the central vitreous.<sup>1,4–6</sup> Vitreous liquefaction actually begins much earlier than detectable by clinical examination or ultrasonography. Postmortem studies have found evidence of liquid vitreous at age 4 years and have observed that by the time the human eye reaches its adult size (ages 16–18 years) approximately 20% of the total vitreous volume consists of liquid vitreous.<sup>40</sup> In these studies of fresh, unfixed postmortem human eyes, it was observed that after age 40 years, there is a steady increase in liquid vitreous, simultaneous with a decrease in gel volume. By age 80–90 years, more than half the vitreous body is liquid. The finding that the central vitreous is where fibers are first observed is consistent with the concept that breakdown of the normal hyaluronan–collagen association results in simultaneous vitreous liquefaction and aggregation of collagen fibrils into bundles of parallel fibrils, seen as large fibers (see Fig. 6.4.4).<sup>1,4–6</sup> In the posterior vitreous, such age-related changes often form large pockets of liquid vitreous, recognized clinically as lacunae, or pockets.<sup>4–6</sup>

The mechanism of vitreous liquefaction is not well understood. Gel vitreous can be liquefied in vivo through the removal of collagen by exogenous enzymatic destruction of the collagen network.<sup>42</sup> It has also been shown that the injection of chondroitinase can induce liquefaction and “disinsertion” of the vitreous.<sup>43</sup> Ocriplasmin is another agent that can induce vitreous liquefaction.<sup>26–28,44</sup> Because of its ability to also induce dehiscence at the vitreous–retinal interface,<sup>45</sup> this agent received approval for pharmacological vitreolysis.<sup>27,28</sup>

Endogenous vitreous liquefaction may be the result of changes in the minor glycosaminoglycans and chondroitin sulfate profile of vitreous.<sup>4,8,10</sup> Another possible mechanism is a change in the conformation of hyaluronan molecules with aggregation or cross-linking of collagen molecules. Singlet oxygen can induce conformational changes in the tertiary structure of hyaluronan molecules. Free radicals generated by metabolic and photosensitized reactions could alter hyaluronan and/or collagen structure and trigger a dissociation of collagen and hyaluronan molecules, which ultimately results in liquefaction.<sup>46</sup> This is plausible because the cumulative effects of a lifetime of daily exposure to light may influence the structure and interaction of collagen and hyaluronan molecules by the proposed free radical mechanism(s).

Biochemical studies support the rheological observations. Total vitreous collagen content does not change after age 20–30 years. However, in studies of a large series of normal human eyes obtained at autopsy, the collagen concentration in the gel vitreous at age 70–90 years (approximately 0.1 mg/mL) was twofold greater than at age 15–20 years (approximately 0.05 mg/mL).<sup>4,40</sup> Because the total collagen content does not change, this finding most likely reflects the decrease in the volume of gel vitreous that occurs with aging and consequent increase in the concentration of the collagen that remains in the gel. The collagen fibrils in aging vitreous gel

**Fig. 6.4.8 Vitreous Structure in Childhood.** (A) The posterior and central vitreous in a 4-year-old child has a dense vitreous cortex with hyalocytes. A substantial amount of vitreous extrudes into the retrocortical (preretinal) space through the premacular vitreous cortex (arrows). However, no fibers are present in the vitreous. (B) Central vitreous structure in an 11-year-old child has hyalocytes in a dense vitreous cortex. No fibers are seen within the vitreous body.

become packed into bundles of parallel fibrils,<sup>3,17</sup> likely with cross-links between them. In patients with diabetes, abnormal collagen cross-links have been identified in the vitreous body, a phenomenon that has been described for other extracellular matrices in patients with diabetes. These findings are consistent with the existence of a diabetic vitreopathy,<sup>47</sup> independent of diabetic retinopathy. The structural effect of these biochemical and rheological changes consists of a transition from a clear vitreous in youth (Fig. 6.4.8), to a fibrous structure in the adult (see Fig. 6.4.4), which results from aggregation of collagen fibrils.<sup>3,4</sup> In patients with diabetes, this occurs earlier in life because of nonenzymatic glycation of vitreous collagen.<sup>47</sup> In old age, advanced liquefaction (synchysis; see Fig. 6.4.5) ultimately leads to collapse (syneresis) of the vitreous and posterior vitreous detachment (PVD).<sup>39</sup>

The vitreous base posterior to the ora increases in size with advancing age to nearly 3 mm, bringing the posterior border of the vitreous base closer to the equator.<sup>48</sup> This widening of the vitreous base was found to be most prominent in the temporal portion of the globe. The posterior migration of the vitreous base probably plays an important role in the pathogenesis of peripheral retinal breaks and rhegmatogenous retinal detachment. Within the vitreous base, a “lateral aggregation” of the collagen fibrils is present in older individuals,<sup>49</sup> similar to aging changes within the central vitreous.<sup>4,17,39,41</sup> Studies<sup>50</sup> have confirmed posterior migration of the posterior border of the vitreous base during aging and also demonstrated intra-retinal synthesis of collagen fibrils that penetrate the ILM of the retina and “splice” with vitreous collagen fibrils. These aging changes at the vitreous base could contribute to increased traction on the peripheral retina promoting retinal tears and detachment.

## Posterior Vitreous Detachment

The most common age-related event in the vitreous body is PVD,<sup>39</sup> defined as separation between the posterior vitreous cortex and the ILM of the

retina. PVD can be localized, partial, or total (up to the posterior border of the vitreous base). Autopsy studies have revealed that the incidence of PVD is 63% by the eighth decade,<sup>51</sup> but more commonly in myopic eyes, where PVD occurs, on average, 10 years earlier than in emmetropic and hyperopic eyes. Cataract extraction in myopic eyes introduces additional effects that promote PVD.<sup>4</sup>

Vitreous liquefaction in conjunction with weakening of vitreoretinal adhesion both result in PVD. It is likely that the dissolution of the posterior vitreous cortex–ILM adhesion at the posterior pole allows liquid vitreous to enter the retrocortical space via the prepapillary hole and perhaps also the premacular vitreous cortex. With rotational eye movements, liquid vitreous can dissect a plane between the vitreous cortex and the ILM, resulting in true PVD. This volume displacement from the central vitreous to the preretinal space causes vitreous syneresis (collapse).

Johnson<sup>39</sup> has proposed that this process of hydrodissection follows a 5-stage (0–4) sequence that is influenced by variations in vitreoretinal adhesion. Stage 0 is complete attachment throughout the fundus. Stage 1 involves detachment of the perifoveal posterior vitreous cortex, probably because this is the area where the liquefied gel first gains access to the retrocortical/preretinal space. There is persistent vitreofoveal adhesion at stage 1. A 500- $\mu$ m diameter area of strong vitreoretinal adhesion in the foveola does not detach until stage 2, at which time there is complete macular separation. In stage 3, there is PVD involving the entire retina except for the vitreopapillary zone, a site of strong vitreoretinal adhesion and thus is the last site of vitreoretinal separation. In stage 4, there is release of the vitreopapillary adhesion and total PVD. It is this last stage that is most often symptomatic.

In 1935, Moore<sup>52</sup> described “light flashes” as a common complaint that results from PVD. Wise<sup>53</sup> noted that light flashes occurred in 50% of cases at the time of PVD; they were usually vertical and temporally located. Voerhoeff<sup>54</sup> suggested that the light flashes result from the impact of the detached posterior vitreous cortex on the retina during eye movement.

“Floaters” are a symptom experienced by patients with PVD. These result from entopic phenomena caused by condensed vitreous fibers, glial tissue of epipapillary origin that adheres to the posterior vitreous cortex, the dense collagen matrix of the posterior vitreous cortex,<sup>4</sup> or less commonly intravitreal blood. Vitreous floaters move with vitreous displacement during eye movement and scatter incident light, which casts a shadow on the retina that is perceived as a gray, “hair-like” or “fly-like” structure. Given time, symptomatic floaters often become less noticeable. Treatment of symptomatic floaters can be performed. YAG laser treatments are performed by some practitioners.<sup>55</sup> There is only evidence for improvement following YAG laser treatments for Weiss’ ring, not other vitreous opacities. Limited vitrectomy can safely and effectively cure the condition (see below).

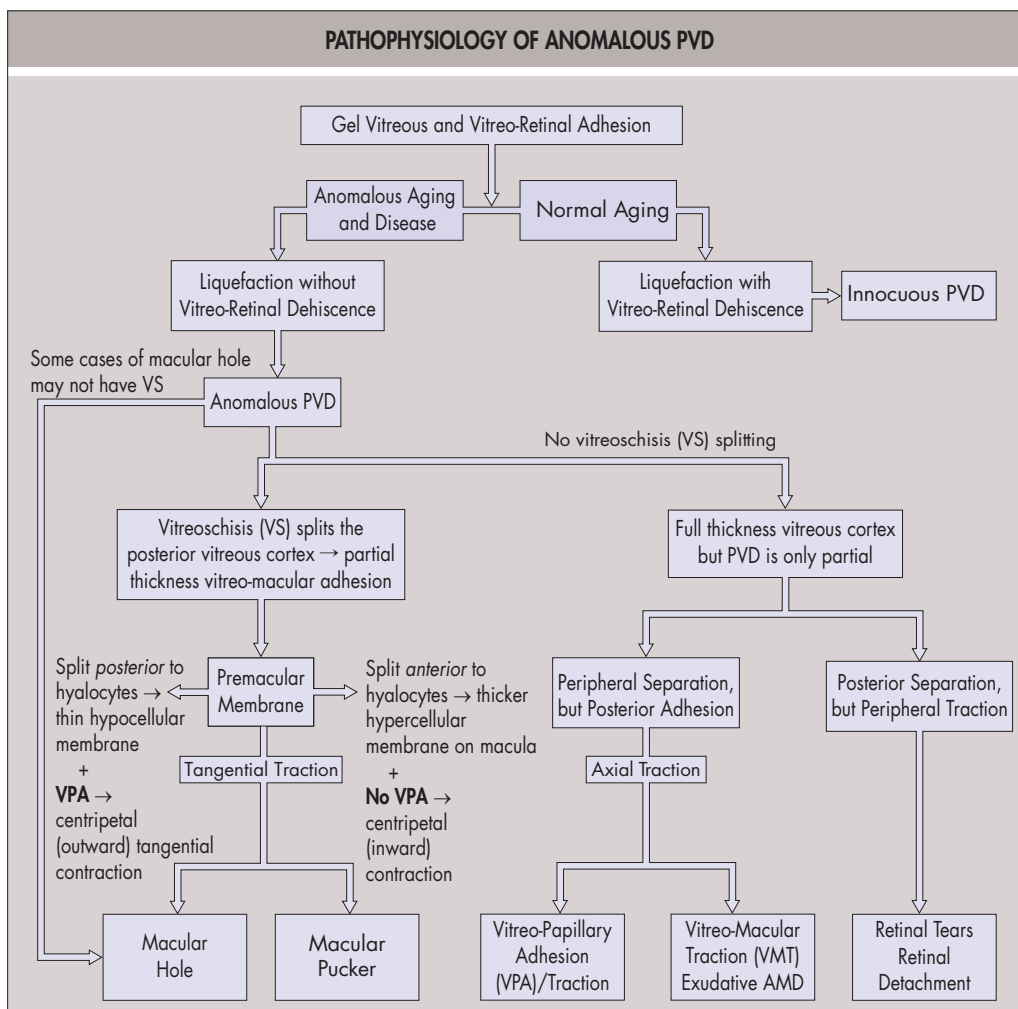

## Anomalous Posterior Vitreous Detachment

Anomalous posterior vitreous detachment<sup>56</sup> occurs when there is extensive vitreous liquefaction without concurrent weakening of vitreoretinal adhesion, resulting in traction at the vitreous–retinal interface. There are various causes for an imbalance between the degree of gel liquefaction and weakening of vitreoretinal adhesion. As described above, inborn errors of collagen metabolism, such as those present in Marfan’s syndrome, Ehlers–Danlos syndrome, and Stickler’s syndrome,<sup>38</sup> result in extensive gel liquefaction at an early age when there is still considerable vitreoretinal adhesion. The result is a high incidence of large posterior retinal tears and detachments. Systemic conditions, such as diabetes induce biochemical<sup>57</sup> and structural<sup>58</sup> alterations in vitreous, known as *diabetic vitreopathy*,<sup>47</sup> which are important in the pathobiology of proliferative diabetic vitreoretinopathy and diabetic macular edema. However, the overwhelming majority of cases are likely caused by an as-yet-unidentified genetic predisposition for firm vitreoretinal adhesion, probably related to the extracellular matrix between vitreous and the retina. Fig. 6.4.9 delineates the various deleterious effects of anomalous PVD.

When the entire (full-thickness) posterior vitreous cortex separates from the macula but is still attached peripherally, there can be vitreoretinal traction causing peripheral retinal tears and detachments. Autopsy studies have found that PVD is associated with retinal breaks in 14.3% of all cases. Patients without diabetes who experience nontraumatic vitreous hemorrhage have retinal tears in up to 67% of cases<sup>59</sup> and retinal detachments in up to 39%<sup>59</sup> of cases.

Posterior full-thickness vitreomacular adhesion with peripheral vitreoretinal separation can pull on the macula and induce vitreomacular traction syndrome. Persistent vitreomacular adhesion may exacerbate age-related

**Fig. 6.4.9 Schematic of Anomalous Posterior Vitreous Detachment.** Vitreous gel liquefaction without concurrent dehiscence at the vitreous–retinal interface causes various anomalies. If separation of vitreous from retina is full-thickness in the axial plane but incomplete in the coronal plane, there can be different forms of partial posterior vitreous detachment (PVD) (right side of diagram). Posterior separation with persistent peripheral attachment can induce retinal breaks and detachments. Peripheral vitreoretinal separation with persistent full-thickness vitreomacular adhesion (VMA) can induce vitreomacular traction syndrome (VMTS). VMA is associated with exudative age-related macular degeneration (Exud AMD) and diabetic macular edema. Persistent attachment to the optic disc can induce vitreopapillopathies and also contribute to neovascularization and vitreous hemorrhage in ischemic retinopathies as well as play a role in macular hole pathophysiology. During PVD, if the posterior vitreous cortex splits (vitreoschisis) anterior to the level of the hyalocytes, a relatively thick, cellular membrane remains attached to the macula. If there is also separation from the optic disc, inward (centripetal) contraction induces macular pucker. If the split is posterior to the hyalocytes, the remaining premacular membrane is relatively thin and hypocellular. Persistent vitreopapillary adhesion (present in 87.5% of cases) results in outward (centrifugal) tangential traction (especially nasally), inducing a macular hole. (From Sebag J. Anomalous PVD—a unifying concept in vitreo-retinal diseases. *Graefes Arch Clin Exp Ophthalmol* 2004;242:690–8; Sebag J. Vitreous and vitreo-retinal interface. In: A. Schachar, editor. *Ryan's Retina*. London: Elsevier; 2018, Ch 23, pp 544–581.)

macular degeneration (AMD). It is not clear by what mechanism this occurs, but patients with dry AMD have a two- to threefold higher prevalence of total PVD, whereas patients with wet AMD have a three- to fourfold higher prevalence of vitreomacular adhesion,<sup>60–62</sup> but these conditions were not influenced by genetic or environmental factors. It is hypothesized that vitreomacular traction could induce low-grade inflammation and/or that the adherent posterior vitreous cortex could alter macular oxygenation from ciliary body and the egress of proangiogenic cytokines from the macula. Similarly, traction on the optic disc can induce vitreopapillary traction syndromes<sup>63</sup> or exacerbate neovascularization with vitreous hemorrhage in proliferative diabetic retinopathy. Moreover, persistent vitreopapillary adhesion may promote macular hole formation as opposed to macular pucker.<sup>64,65</sup>

Anomalous PVD can be associated with splitting of the posterior vitreous cortex, called *vitreoschisis*.<sup>66</sup> This may be the first event in macular pucker and some cases of macular hole pathogenesis.<sup>67,68</sup> Vitreoschisis may also be present in diabetic macular edema.<sup>69</sup> Autopsy studies<sup>70</sup> have reported that PVD was associated with vitreous cortex remnants at the fovea in 26 of 59 (44%) human eyes. Recent studies<sup>67,68</sup> employing combined optical coherence tomography and scanning laser ophthalmoscopy imaging detected vitreoschisis in about half the patients with macular pucker and macular holes.

### Premacular (Epiretinal) Membrane/Macular Pucker

The term *epiretinal membrane* (ERM) is a misnomer. The prefix “epi” means adjacent to, so this could refer to subretinal membranes. The premacular membrane (PMM) that causes macular pucker contains astrocytes and retinal pigment epithelial (RPE) cells<sup>80</sup> as well as hyalocytes. Macular pucker begins when vitreoschisis (Fig. 6.4.9) splits the posterior vitreous cortex anterior to hyalocytes leaving a cellular membrane attached to the macula. Contraction is stimulated by connective tissue growth factor.<sup>24</sup> Recent studies<sup>81</sup> have also identified that nearly half of all eyes with macular pucker have more than one site of retinal contraction associated with a higher incidence of intraretinal cysts and significantly more macular

thickening.<sup>81</sup> Following anomalous PVD with vitreoschisis, the PMM can contract inward toward the fovea (centripetal tangential traction) and cause visual impairment and metamorphopsia, sometimes necessitating surgery (see Chapter 6.33).<sup>71</sup>

### Macular Holes

Primary full-thickness macular holes (FTMHs) are caused by anomalous PVD with centrifugal (outward) tangential traction of the PMM accentuated by vitreo-papillary adhesion (Fig. 6.4.9). Secondary macular holes can occur from conditions such as blunt trauma, and lightning strike.

Lamellar macular holes are partial-thickness retinal defects that most commonly occur in association with a thickened posterior premacular membrane (LHEP) in degenerative LMH, or a PMM with pucker in tractional LMH. The prevalence of VPA is greater in the latter than the former (see Chapter 6.32).<sup>82</sup>

### Diabetic Vitreopathy

In diabetes, there is an increase in vitreous glucose levels<sup>72</sup> associated with increased advanced glycation end products.<sup>47,57</sup> In poorly controlled diabetes, fluctuations in systemic glucose levels alter the ionic milieu, influencing vitreous osmolarity and hydration. This could result in swelling and contraction of the entire vitreous body via effects on the very hydrophilic hyaluronan molecules, with consequent traction on structures attached to the posterior vitreous cortex, such as new blood vessels from the optic disc and/or retina.<sup>73</sup> These events could promote the proliferation of neovascular fronds and perhaps even induce rupture of these new vessels with vitreous hemorrhage.

Molecular effects of diabetes result in morphological changes within the vitreous body<sup>47,58</sup> (Fig. 6.4.10). The roles of these and other pathological changes, such as posterior vitreoschisis,<sup>66,69</sup> may lead to therapy designed to inhibit diabetic vitreopathy. Alternatively, the induction of innocuous PVD early in the course of diabetic retinopathy may have long-term salutary effects in patients at great risk.<sup>26–28</sup>

**Fig. 6.4.10 Diabetic Vitreopathy.** (A) Right eye of a 9-year-old girl who has a 5-year history of type 1 diabetes shows extrusion of central vitreous through the posterior vitreous cortex into the retrocortical (preretinal) space. The subcortical vitreous appears very dense and scatters light intensely. Centrally, there are vitreous fibers (arrows) with an anteroposterior orientation and adjacent areas of liquefaction. (B) Central vitreous in the left eye of the same patient shows prominent fibers that resemble those seen in adults without diabetes (see Fig. 6.4.5). (Reprinted with permission from Sebag J. Abnormalities of human vitreous structure in diabetes. *Graefes Arch Clin Exp Ophthalmol* 1993;231:257–60.)

## Asteroid Hyalosis

This generally benign condition is characterized by small, yellow-white, spherical opacities throughout the vitreous body. An autopsy study<sup>74</sup> of 10801 eyes found an incidence of 1.96%; with a male/female ratio of 2:1. Asteroid hyalosis is unilateral in greater than 75% of cases. Asteroid bodies are associated intimately with the vitreous gel and move with vitreous displacement during eye movement, suggesting a relationship with age-related collagen fibril degeneration.<sup>74</sup> However, PVD, either complete or partial, occurs less frequently in individuals with asteroid hyalosis than in age-matched controls,<sup>75</sup> and this finding does not support age-related degeneration as a cause. Histological studies demonstrate a crystalline appearance and a pattern of positive staining to fat and acid mucopolysaccharide stains that is not affected by hyaluronidase pretreatment.<sup>76</sup> Electron diffraction studies have shown the presence of calcium oxalate monohydrate and calcium hydroxyphosphate. Ultrastructural studies have revealed

intertwined ribbons of multilaminar membranes (with a 6-nm periodicity), which are characteristic of complex lipids, especially phospholipids, that lie in a homogeneous background matrix.<sup>77</sup> In these investigations, energy-dispersive X-ray analysis showed calcium and phosphorus to be the main elements in asteroid bodies. Electron diffraction structural analysis demonstrated calcium hydroxyapatite and possibly other forms of calcium phosphate crystals.

Some reports have suggested an association between asteroid hyalosis and diabetes mellitus,<sup>78–81,83</sup> whereas other investigations found no such association.<sup>84</sup> Asteroid hyalosis appears to be associated with certain pigmentary retinal degenerations,<sup>83</sup> although it is not known whether this is related to the presence of diabetes in these patients. Yu and Blumenthal<sup>85</sup> proposed that asteroid hyalosis results from aging collagen, whereas other studies<sup>86</sup> have suggested that asteroid formation is preceded by depolymerization of hyaluronan.

The most interesting aspect of asteroid hyalosis is the marked absence of patient complaints and symptoms. Although it can be difficult, in some cases, to examine and image the fundus, these patients often experience no visual disturbances, whereas patients with PVD can be markedly symptomatic.<sup>87,88</sup> It is hypothesized that the explanation is related to the smooth surfaces of asteroid bodies that may not scatter light in as disturbing a fashion as the irregular surfaces of the collagen matrix in the detached posterior vitreous cortex and/or the collagen fibrils of the vitreous body.<sup>3,4,17,39</sup> The condition of “Vision Degrading Myodesopsia” can be safely cured with limited vitrectomy that normalizes contrast sensitivity function.<sup>89</sup>

# Contact B-Scan Ultrasonography

Yale L. Fisher, Dov B. Sebrew

# 6.5

**Definition:** Diagnostic technique that is useful in the evaluation of intraocular and orbital contents.

## Key Features

- High-frequency sound waves are emitted and received by a handheld transducer probe.
- Images are processed and displayed on a video monitor.

## Associated Features

- Adequate interpretation for diagnosis of posterior segment disease depends on three concepts:
  - Real time.
  - Gray scale.
  - Three-dimensional analysis.

## INTRODUCTION

Ophthalmic ultrasonography is a useful diagnostic technique for intraocular and orbital evaluation, especially in the setting of opaque media. It involves pulse-echo technology, in which high frequency sound waves are emitted from a handheld transducer probe. Returning echoes are processed and displayed on video monitors or oscilloscopes.

Two modes of display are common:

- A-scan mode (time-amplitude), used predominantly for interpretation of tissue reflectivity—the returning echoes form a graph-like image seen as vertical deflections from a baseline.

- B-scan mode (intensity modulation), used predominantly for anatomical information—it shows cross-sectional images of the globe and orbit.

Both types of sonographic display are complementary. This chapter focuses on B-scan information.

Developed in the mid-1950s with water-immersion techniques, B-scan ultrasonography initially required a laboratory setting. In the early 1970s, contact devices utilizing methylcellulose or a similar sound-coupling agent were introduced, and this rapidly increased the availability and popularity of B-scan ultrasonography. Subsequent improvements in image quality and scanning rates made interpretation easier for the examiner.<sup>1-8</sup>

## DEVICES

Commercially available instruments for ocular and orbital contact B-scan ultrasonography usually employ 10-MHz (megahertz; megacycles per second) handheld transducer probes. A motor within the handpiece moves the ultrasonic source in a rapid sector scan to create cross-sectional B-scan images. These devices have resolution capacities of approximately 0.15 mm axially and 0.3 mm laterally. Most contact B-scan machines are freestanding and relatively mobile; they consist of a detachable transducer probe, a signal-processing box, and a display screen. Self-contained processing probes, which are capable of integrating with independent computer laptops or desktop units, are also available. (Video 6.5.1)

## TECHNIQUE OF EXAMINATION

The handheld ultrasonic probe is placed gently against the eyelid or sclera by using a sound-coupling agent, such as methylcellulose or, preferably, heat-sensitive ophthalmic gel. The ultrasonographer can move the probe systematically to scan the globe and orbit. Avoiding the lens system of the globe is important to prevent image artifacts (Fig. 6.5.1).

**Fig. 6.5.1** Illustration demonstrating placement of handheld ultrasonic probe and corresponding B-scan image with optic nerve (arrow) as reference point. (Additional material for ultrasound education available at <http://www.OphthalmicEdge.org>.)

## CONCEPTS OF B-SCAN INTERPRETATION

Interpretation of a B-scan ultrasonogram depends on three concepts:

- Real time.
- Gray scale.
- Three-dimensional analysis.

### Real Time

Ultrasound B-scan images are visualized at approximately 32 frames/sec, allowing motion of the globe and vitreous to be detected. Characteristic real-time movements are useful for identifying tissues. Detached retinal movement, for example, appears as a slow undulation, whereas vitreous movements are usually more rapid. Real-time ultrasonic information is often critical to surgical decisions.

### Gray Scale

A variable gray-scale format displays the returning echoes as intensity-modulated dots. Strong echoes, such as those seen from sclera or detached retina, are displayed brightly at high instrument gain and remain visible even when the gain is reduced. Weaker echoes, such as those from vitreous hemorrhage, are seen as lighter shades of gray that disappear when gain is reduced. Because comparison of echo strengths is critical to tissue analysis, the examiner must ensure that all the returning echoes are captured and displayed. Perpendicularity to the object of regard ensures adequate comparable interpretive signals.

### Three-Dimensional Analysis

Developing a mental three-dimensional image or anatomical map from multiple two-dimensional B-scan images is the most difficult concept to master. The examiner must learn to create a mental topographical map of the eye or orbit from as many imaging views as required. Three-dimensional understanding of ultrasound images is especially critical in the preoperative evaluation of complex retinal detachments and intraocular or orbital tumors.

## DISPLAY PRESENTATION AND DOCUMENTATION

Posterior B-scan images displayed on a screen are presented horizontally. Areas closest to the probe are imaged to the left of the screen, and those farthest away are imaged to the right. The top of the screen correlates with a manufacturer's mark located on the examining probe that represents the initial transducer sweep for each sector scan. Registration of the screen is critical to understanding and interpreting examinations. Movement of the probe from one position to another changes the registration, making instant re-evaluation by the examiner an absolute necessity. Contact B-scan ultrasonography is a dynamic examination. Individual "frozen" cross-sectional images used for documentation should not alone be used for interpretation. (Video 6.5.1)

See clip:  
6.5.1

### Normal Vitreous Cavity

The normal vitreous space is almost clear echogenically. Occasional small dots or linear echoes can be seen at the highest gain settings (90 decibels [dB]), but they fade rapidly as the gain is reduced. Real-time scanning during eye movement usually shows some motion of these fine echoes as well as the position of the vitreous face.

### Vitreous Hemorrhage

Intravitreal hemorrhage produces easily detectable diffuse dots and blob-like vitreous echoes that correlate with the amount of blood present. Reduction of gain to 70 dB results in rapid fading of all but the densest areas of reflectivity. Real-time evaluation usually shows a characteristic rapid motion during command voluntary eye movement.

### Retinal Detachment

Detached retina appears as a highly reflective sheet-like tissue within the vitreous space (Fig. 6.5.2). Small detachments often appear dome-like on

**Fig. 6.5.2 Contact B-Scan Image of a Retinal Detachment.** This axial section of a total retinal detachment reveals a highly reflective sheet-like membrane (arrows) in the vitreous space, detached from the posterior eye wall and attached only to the optic nerve head.

imaging. The appearance of total retinal detachment, which anatomically is cone shaped, varies, depending on the position of the examining probe. Axial images are funnel shaped with attachment to the optic nerve head. Coronal images show a circular cross-section of the cone.

Although recent detachments have a characteristic undulating movement slower than that of the vitreous gel, long-standing detachments appear stiff because of proliferation of scar tissue on the retinal surface.

### Choroidal Detachment

Detached choroid appears smooth and convex on imaging. An elevated dome is usually localized between the pars plana and the posterior equator of the globe. Serous choroidal detachments are echolucent within the suprachoroidal space, whereas hemorrhagic choroidal detachments appear reflective. Clotted blood is highly reflective, whereas liquefied blood is usually less so and more mobile during ocular movement. When severe, the detached choroid can meet at the center of the globe producing retina-to-retina touch, often termed "a kissing choroidal."

A choroidal detachment can be differentiated from a retinal detachment by its location, shape, thickness, and movement.

### Tumors

Evaluation of intraocular tumors requires not only topographical localization but also interpretation of gray-scale characteristics. Malignant choroidal melanomas, for example, have the most characteristic ultrasonic appearance. They are mostly dome shaped or mushroom shaped, and on gray scale, their anterior borders are strongly reflective, whereas the progressively deeper portions of the tumor are less reflective. This is caused by cellular homogeneity that provides a false hollowing appearance. Tissues, such as orbital fat, localized behind these tumors are often shadowed and appear less reflective as a result of absorption of sound by the tumor.

## DIGITAL CONTACT ULTRASONOGRAPHY

Advances in electronic and digital software have made the greatest changes in diagnostic ultrasonography. High-capacity computer memory has revolutionized storage, recall, and transmission of real-time movie segments for documentation and review.

## WHAT'S NEW?

### Anterior Segment High-Frequency Ultrasonography

Although most B-scan focuses on the posterior segment of the globe or the anterior orbit, higher-frequency instruments in the range of 30–100 MHz are available for anterior segment imaging. Penetration of sound at these

frequencies remains limited (approximately 4–5 mm), but resolution is greatly augmented (at 40 MHz: axial 23 microns; lateral 35 microns).

Recent development of digital imaging and specialized software has improved availability of this technology. Furthermore, the examination technique has become less time consuming and more patient friendly, with the introduction of modified, sterile, single-use slip on water condoms covering the exposed and moving transducer.

With a simple adjustment of software, clear images of the anterior segment are now possible. These images can complement posterior segment evaluations, especially in complex scenarios of opaque media and abnormalities behind the iris, within the ciliary body, or involving the pars plana.

Axial, radial, and coronal images in real time are accumulated and stored as easily as posterior segment images.<sup>9</sup>

## SUMMARY

Contact B-scan ultrasonography provides a convenient, noninvasive means for the dynamic examination of the vitreoretinal relationship and the evaluation of intraocular structures in situations where clinical examination is not possible because of opaque media. Three-dimensional and digital technology expands teaching capability and brings the clinical availability of contact ultrasonography to a larger audience. Ultrasound studies should, however, be used in conjunction with detailed clinical examination and other investigational modalities.

# Camera-Based Ancillary Retinal Testing: Autofluorescence, Fluorescein, and Indocyanine Green Angiography

6.6

*Eric Feinstein, Jeffrey L. Olson, Naresh Mandava*

**Definition of Fluorescein Angiography:** Fluorescein angiography (FA) is a diagnostic technique that uses intravenous or oral fluorescein dye to allow the sequential visualization of blood flow simultaneously through retinal, choroidal, and iris tissue.<sup>1</sup> Since its introduction, it has been an invaluable aid in the diagnosis, management, and treatment of chorioretinal diseases.<sup>1,2</sup>

## Key Features

- Intravenous or oral dose of fluorescein sodium dye administered.
- Sequential fundus photographs obtained by using a camera equipped with appropriate exciting and absorbing filters or light sources taking advantage of the inherent fluorescent properties of the dye.
- Reflected light captured on either film or as digital images.
- Interpretation of images critically dependent on an understanding of ocular anatomy in both health and disease.
- Indocyanine green dye, administered intravenously, can be an important adjunct to the diagnosis of chorioretinal disease.

**Definition of Indocyanine Green Angiography:** Indocyanine green angiography (ICGA) is a diagnostic technique that exploits indocyanine green (ICG) dye's infrared fluorescence and biochemical properties to adequately portray the characteristics of the choroidal circulation, aiding in the diagnosis of diseases affecting the choroid, such as idiopathic polypoidal choroidal vasculopathy, exudative age-related macular degeneration (AMD), and inflammatory diseases, among others.<sup>3-5</sup>

## Key Features

- Intravenous injection of indocyanine green dye.
- Serial photographs taken with digital imaging system to capture emission for dye.
- Interpretation of resultant images critically dependent on understanding of retinal and choroidal anatomy in health and disease.

**Definition of Fundus Autofluorescence:** Fundus autofluorescence (FAF) is a noninvasive retinal imaging modality used in clinical practice to map out density of lipofuscin within the retinal pigment epithelium (RPE).

## Key Features

- Intrinsic fluorescence emitted by lipofuscin within the RPE after being excited with short to medium wavelength visible light.
- Photographs can be taken with a scanning laser ophthalmoscope (SLO) or standard/wide-field fundus camera.
- Interpretation of resultant images helps to detect and track changes in lipofuscin accumulation, which corresponds to the health and function of the RPE.

## FLUORESCEIN ANGIOGRAPHY

### Introduction

Fluorescein angiography (FA) relies on the special fluorescent property of sodium fluorescein (SF)—defined as the ability of certain molecules to emit light of longer wavelength when stimulated by light of shorter wavelength. After stimulation, electrons return to their base energy level, emitting energy in the form of electromagnetic waves producing visible light.<sup>3-5</sup> The dye has a narrow spectrum of light absorption, with the maximum peak at 490 nm (485–500 nm, blue visible spectrum). Emission (fluorescence) occurs in the yellow-green spectrum with a wavelength of 530 nm (520–535 nm).<sup>3</sup>

A stimulation source transmits light energy to the patient's retina using either a flash/filter or laser in the 485–500 nm range. The energy is then either reflected back by the retina as blue light, or absorbed by the SF and emitted back as green light. A capturing device (camera) uses a green filter (520–535 nm) to selectively save the fluorescent image onto film or a digital surface.

### Purpose of the Test

In normal individuals, the SF molecule freely crosses the wall of highly permeable capillaries (choriocapillaris) but remains within the lumen of retinal and larger choroidal vessels because a good percentage circulates through the blood unbound to plasma proteins. This makes FA the ideal study for evaluating retinal circulation, its vascular architecture, and the status of the inner and outer blood–retinal barrier. Information from the FA can also be used to study the choroidal circulation and retinal pigment epithelial (RPE) cells.<sup>6,7</sup> Vascular diseases, such as diabetic retinopathy, central serous chorioretinopathy, venous occlusive disease, and choroidal neovascularization secondary to age-related macular degeneration (CNV-AMD), can be clearly demonstrated with FA. These images are used to select the appropriate therapeutic approach, guide treatment, and assess therapeutic results.<sup>8</sup>

### Properties of Sodium Fluorescein Dye

SF (sodium resorcinolphathalein) is a yellow-red, synthetic salt dye that is most commonly used to evaluate flow patterns of subterranean waters, as a cosmetic and pharmacological color, and as a labeling agent in protein research.<sup>9</sup> It has a molecular weight of 376.7 kilodaltons (kDa).<sup>10</sup> Once

injected to the bloodstream, approximately 80% of the dye becomes bound to plasma proteins (particularly albumin), and the rest remains unbound.<sup>10</sup> The dye is metabolized by the liver and kidneys and is eliminated in the urine within 24–36 hours of injection. Its most important property for ophthalmological purposes is its fluorescence. It has a narrow spectrum of absorption and excitation that makes the FA technique feasible (see “Introduction”). SF dye is readily available and produced commercially in aliquots of 2–3 mL of 25% or 5 mL of 10% sterile aqueous solution.

## Procedure

A good quality FA is highly dependent on a high-resolution fundus camera, a skilled photographer, and a clear view to the retina.

The spherical refractive error of the patient is corrected by simultaneously focusing the cross-hairs in the eyepieces reticule and the fundus. The focusing wheel is used only for fine focus. Most cameras are equipped with a joystick to help align the camera to the patient's eye. Proper alignment gives even illumination of the fundus, whereas misalignment results in peripheral and central artifacts in the images. This can be ameliorated with careful lateral movements of the joystick. Variable amounts of magnification can usually be selected, depending on the system, and this should be tailored to the pathology being examined.

Pharmacological mydriasis is usually required for most commercially available equipment, but there are a few that do not require it. Before starting the infusion of the dye, a set of baseline red-free images are taken using a green filter. Green light provides excellent contrast and enhances the visibility of the retinal vasculature and vitreous–retinal interface. It is particularly useful in assessing retinal hemorrhages, drusen, epiretinal membranes, and exudates.

The dye is typically injected in the antecubital vein with a 21-gauge butterfly needle in a rapid but controlled infusion ( $\approx 1$  mL/sec) to maximize the contrast of the early filling phase of the angiography.<sup>7,11</sup> Although there is no evidence of increased side effects when using higher concentrations of the dye, many practitioners prefer to use a smaller volume of a more concentrated solution. The two preferred doses are 2.5 mL of a 20% solution and 5 mL of a 10% solution. If the patient is a newborn or premature baby, a 10% solution at a dose of 0.1 mL/kg followed by an isotonic saline flush is recommended.<sup>12</sup> Infusion of the dye can be done from the left or right antecubital vein without changing the times or image qualities. If the patient has undergone mastectomy with lymph node dissection, the dye should probably not be injected in the ipsilateral arm because of the risk of altered lymphatic flow.<sup>9</sup>

Extravasation of the dye should be avoided, as infiltration is painful and may rarely lead to tissue necrosis. A timer is started after injection of the dye, and image acquisition should begin immediately to capture initial choroidal and retinal filling. Photographs are usually taken at 4-second intervals, beginning 15 seconds before injection and continuing with a tapered frequency for 10–20 minutes. However, the timing and the interval between exposures should be adjusted on the basis of the pathology that is being studied. For instance, a choroidal neovascular membrane leaks profusely early in the study; therefore, photographs should be taken with more frequency at the beginning of the study to capture the details of the membrane.

## Complications

FA is an invasive test, and despite being deemed generally safe, it is not free of adverse reactions, ranging from mild to severe. Mild reactions are defined as transient and resolve spontaneously without treatment. Most commonly these are nausea (approximately 3%–15%), vomiting (up to 7%), sneezing, inadvertent arterial injection, and pruritus.<sup>1,13</sup> Moderate adverse reactions resolve with medical intervention. These include urticaria, angioedema, syncope, thrombophlebitis, pyrexia, local tissue necrosis, and nerve palsy.<sup>13</sup> Severe reactions require intensive intervention, and the patients may have poor recovery. These reactions include laryngeal edema, bronchospasm, anaphylaxis, hypotension, shock, myocardial infarction, pulmonary edema, hemolytic anemia, cardiac arrest, tonic-clonic seizures, and death.<sup>1,13</sup> The incidence of adverse reactions has been described in the report on a multicenter, collaborative study (Table 6.6.1).<sup>13</sup> The overall incidence of complications is estimated to be 3%–20%. Although not considered a complication, the yellowing of skin, most commonly in fair-skinned individuals, may lead to photosensitivity, and patients should be cautioned about exposure to ultraviolet rays. Recently, a case of extensive jaundice following fluorescein was reported.<sup>14</sup> Patients should also be advised about possible darkening of urine for 24–48 hours after the study.

**TABLE 6.6.1 Incidence of Adverse Reactions to Intravenous Fluorescein Angiography**

	Reaction	Incidence
Mild	Nausea, vomiting, sneezing	0%–5% (based on 87% of respondents)
	Urticaria	1:82
Moderate	Syncope	1:337
	Other	1:769
	<b>Overall</b>	<b>1:63</b>
	Respiratory	1:3800
	Cardiac	1:5300
Severe	Seizures	1:13900
	Death	1:221781
	<b>Overall</b>	<b>1:1900</b>

From the survey conducted by Yannuzzi LA, Rohler KT, Tindel LJ, et al. Fluorescein angiography complication survey. Ophthalmology 1986;93:611–7.

Previous efforts to relate the procedure technique, dye concentrations, and rate of infusion and volume with the incidence of adverse reactions have been inconclusive.<sup>7</sup> Although in vivo skin tests remains the most reliable diagnostic tool for the diagnosis of immunoglobulin E–mediated allergy to SF (including severe cases of anaphylaxis), it is not particularly effective in predicting mild adverse reactions (ARs) because they are not attributable to immunological mechanisms.<sup>11</sup> Special attention should be paid to patients with reported previous mild or moderate ARs during the study because the rate of recurrence is high (48%–68%), and the study should be avoided, if possible.<sup>1</sup>

The American Academy of Ophthalmology Preferred Practice Patterns states that each angiographic facility should have in place an emergency protocol to minimize risk and manage complications.<sup>15</sup> Regular stocking and updating of medications is needed, as well as regular training of photographers and supporting staff to recognize signs and symptoms of anaphylaxis. An emergency kit should be available on site and should include an airway bag, intravenous equipment, automated external defibrillator, oral or intramuscular antihistamines, and autoinjectors of epinephrine. The protocol should be posted in a prominent place and be visible to everybody.<sup>15</sup>

Although package inserts from most brands of SF dye state that its use should be avoided during pregnancy, especially during the first trimester, data from several series and animal studies have not been able to identify a higher rate of birth abnormalities or complications (regardless of SF concentration: 10% or 25%).<sup>12,16,17</sup> It is therefore reasonable to perform FA on pregnant patients when vision is threatened by potentially blinding diseases. Nonetheless, most clinicians prefer to wait until after delivery. Nursing mothers are discouraged from breastfeeding for at least 24–48 hours after FA.<sup>18</sup>

Several technological advances have taken place since the introduction of film angiography:

- *Confocal scanning laser ophthalmoscope (CSLO) as the energy source:* The main benefit of switching to CSLO instead of a traditional cobalt blue flashbulb is that the exact laser wavelength can be selected to generate the peak emission of light of the SF dye.<sup>2,9</sup> This means a significant increase of the signal-to-noise ratio in each examination. Despite the fact that the retina receives a higher emission of light energy with this modality, the toxic threshold is not exceeded because the energy is emitted only for 0.1–0.7 microseconds.<sup>19</sup> This enables high-speed acquisition of images and short movies, allowing a dynamic evaluation of the blood flow through the retinal and choroidal vessels. The wavelength of the laser can be tuned or combined to acquire images with different dyes simultaneously (SF and indocyanine green). The procedure is more comfortable for the patient because there is no bright flash (Fig. 6.6.1).<sup>9,19</sup>
- *The change of film to digital images:* The development of high-resolution (high-definition [HD]) cameras along with computers with higher storage capacity has allowed digital equipment to mostly supplant traditional film equipment.<sup>3,4,6</sup> Digital images can have a similar or greater resolution than that of a traditional film-based one (4096 × 2736 pixels).<sup>6</sup> The coupling of CSLO with pinhole cameras effectively blocks scattered light as well as details outside the optical focus. As a result, greater detail in the capillary network becomes visible. And, finally, a digital image enables real-time correction of gain, exposure, and focus, as well as instant visualization, which means better image quality.<sup>4</sup> It also makes the examination and manipulation of the images easier, allows

**Fig. 6.6.1 Fluorescein Angiography (FA) and Indocyanine Green Angiography (ICGA) Images Taken Simultaneously in the Same Patient.** (A) FA image. (B) ICGA image, in which, in addition to the normal fluorescence of the retinal vessels, the deep choroidal vessels are visualized. (Courtesy Jans Fromow-Guerra, MD: Associate Professor. Asociación para Evitar la Ceguera en México, IAP. México DF.)

**Fig. 6.6.2 Example of Ultra-Wide Field Fluorescein Angiography (FA) Images (200° Angle View).** Mid-phase angiogram in a patient with proliferative diabetic retinopathy. Note the neovascularization elsewhere (NVE) along the distance inferotemporal arcades with surrounding areas of nonperfusion and mild leakage from the large vessels. Small areas of punctate hyperfluorescence represent multiple microaneurysms in all quadrants.

**Fig. 6.6.3 Peak Phase Angiogram.** Approximately 25 seconds after injection, maximal fluorescence of the retinal circulation is evident. Note the intricate detail of the perifoveal capillary network.

for the rapid transmission of data by electronic means, and eliminates the need for physical storage space.<sup>4</sup>

- **Wide and ultra-wide angle of view:** Traditionally, the standard angle of view was 30–50° with a 2.5 magnification,<sup>3</sup> making the evaluation of peripheral retinal pathology difficult. Contact lens systems increased the angle of view to up to 160°. A new ultra-wide field system that uses a rotating ellipsoidal mirror with two conjugate focus points combined with a scanning laser ophthalmoscope creates an ellipsoidal surface capable of focusing light rays emanating from the peripheral retina, (up to 200°) (Fig. 6.6.2).<sup>2,20,21</sup> Ultra-wide field angiography has shown to be useful for identification and management of peripheral pathology in various diseases, including diabetes, sickle cell anemia, posterior/panuveitis, and pediatric retinal disease, among others.<sup>21–24</sup>

## Interpretation of Results

### Normal Fluorescein Angiogram

The dye first enters the eye in the short posterior ciliary arteries 10–15 seconds after injection in patients with normal circulation. The dye is then visualized in the choroid and optic nerve head. This initial filling is dependent on the cardiovascular condition and age of the patient as well as the speed of injection. The choroidal circulation is seen initially as the choroidal flush—a mottled and patchy fluorescence created as dye fills the choriocapillaris. The patchy appearance is created as separate lobules of the choriocapillaris fill sequentially. As dye leaks from the choriocapillaris

during the early phases of the angiogram, Bruch's membrane is stained, and choroidal vasculature detail is obscured. A cilioretinal artery is seen simultaneously with the fluorescence of the choroidal circulation in 10%–15% of patients.

One to three seconds after choroidal filling, the retinal circulation begins to fluoresce (at 11–18 seconds). The retinal arterial system should fill completely in about 1 second. The early arteriovenous phase is characterized by the passage of fluorescein dye through the central retinal arteries, the precapillary arterioles, and the capillaries, and the late arteriovenous phase is characterized by the passage of dye through the veins in a laminar pattern. During the late arteriovenous phase, maximal fluorescence of the arteries occurs, with early laminar filling of the veins. Laminar filling of veins is caused by the preferential concentration of unbound fluorescein along the vessel walls. Several factors are responsible for the laminar pattern of venous filling; these include the more rapid flow of plasma along the vessel wall as well as the higher concentration of erythrocytes in the central vascular lumen.

Maximal fluorescence is achieved in the juxtafoveal or perifoveal capillary network after 20–25 seconds. The normal capillary-free zone, or foveal avascular zone, is approximately 300–500 μm in diameter. A dark background to this capillary-free zone in the macula is created by blockage of choroidal fluorescence by both xanthophyll pigment and a high-density of RPE cells in the central macula. This phase of angiography has been termed the *peak phase* because maximal fluorescence of the capillaries and enhanced resolution of capillary detail occurs (Fig. 6.6.3). The management

**BOX 6.6.1 Causes of Hypofluorescence****Blocked Retinal Fluorescence**

- Media opacity
- Vitreous opacification (hemorrhage, asteroid hyalosis, vitritis)
- Subhyaloid hemorrhage.
- Intraretinal pathology (hemorrhage [vein occlusion], edema)

**Blocked Choroidal Fluorescence**

- All entities that cause blockade retinal fluorescence.
- Outer retinal pathology (lipid, hemorrhage, xanthophyll)
- Subretinal pathology (hemorrhage, lipid, melanin, lipofuscin, fibrin, inflammatory material)
- Subretinal pigment epithelium pathology (hemorrhage)
- Choroidal pathology (nevus, melanoma)

**Vascular Filling Defects****Retina**

- Occlusion or delayed perfusion
- Central or branch artery occlusion
- Capillary nonperfusion (diabetes, vein occlusion, radiation, etc.)
- Atrophy or absence of retinal vessels

**Choroid**

- Occlusion of large choroidal vessels or choriocapillaris (sectoral infarct, malignant hypertension, toxemia, lupus, choroidopathy, renal disease)
- Atrophy or absence of choroidal vessels or choriocapillaris (choroideremia, acute multifocal placoid pigment epitheliopathy)

**Optic Nerve**

- Occlusion (ischemic optic neuropathy)
- Atrophy or absence of tissue (coloboma, optic nerve pit, optic nerve hypoplasia, optic atrophy)

of microvascular diseases of the retinal capillaries, such as diabetic macular edema, requires excellent peak phase imaging.

The first pass of fluorescein through the retinal and choroidal vasculature is complete after 30 seconds. The recirculation phases, characterized by intermittent mild fluorescence, follow. After approximately 10 minutes, both the retinal and choroidal circulations generally are devoid of fluorescein. Many normal anatomical structures continue to fluoresce during late angiography, such as the disc margin and optic nerve head. The staining of Bruch's membrane, choroid, and sclera is more visible in patients who have lightly pigmented RPE.

**Abnormal Fluorescein Angiography**

The terms *hypofluorescence* and *hyperfluorescence* are used in the interpretation of fluorescein angiograms. Hypofluorescence is a reduction or absence of normal fluorescence (Box 6.6.1), whereas hyperfluorescence is increased or abnormal fluorescence (Box 6.6.2).

- **Hypofluorescence:** Hypofluorescence can be categorized into *blockage* (masking of fluorescence) or *vascular filling defects*. Blocked fluorescence can provide clues as to the level of the blocking material, such as vitreal, retinal, or subretinal. Only structures or material anterior to the area of fluorescence can block fluorescence. Blocked retinal fluorescence may be caused by any element that diminishes the visualization of the retina and its circulation (Fig. 6.6.4). Blockage of retinal fluorescence also may localize the pathology to the inner retina. The retinal circulation is unique in that the large retinal vessels and precapillary first-order arterioles lie in the nerve fiber layer, whereas the capillaries and post-capillary venules are located in the inner nuclear layer. Flame-shaped hemorrhages are superficial and block all retinal vascular fluorescence, whereas deeper dot or blot hemorrhages (or intraretinal lipid) block capillary fluorescence but do not block larger superficial vessels. Fluorescence may also be blocked by melanin (scars, melanoma, nevus), lipofuscin deposits (Stargardt disease and Best disease), hemorrhage (diabetic retinopathy), and serosanguinous fluid beneath the RPE (CNV-AMD). Vascular filling defects produce hypofluorescence because of the reduced or absent perfusion of tissues. Retinal vascular filling defects can involve large-, medium-, or small-caliber vessels. Capillary nonperfusion manifests as vascular filling defects and is typically seen in common ischemic disease processes, such as diabetic retinopathy and venous occlusive disease (Fig. 6.6.5). Choroidal vascular filling

**BOX 6.6.2 Causes of Hyperfluorescence****Pseudo-fluorescence****Autofluorescence****Transmitted Fluorescence**

- Geographic atrophy
- "Bull's eye" maculopathy
- Macular hole
- Atrophic chorioretinal scar
- Drusen

**Abnormal vessels****RETINA**

- Angioma; Wyburn–Mason syndrome
- Cavernous hemangioma
- Vascular tumor
- Retinoblastoma

**CHOROID**

- Melanoma
- Choroidal neovascularization
- Choroidal hemangioma

**OPTIC NERVE**

- Peripapillary vascular loops

**Leakage****RETINAL VESSELS**

- Venous occlusive disease
- Frosted angiitis
- Phlebitis

**NEOVASCULARIZATION**

- Diabetes retinopathy
- Radiation retinopathy
- Sickle cell retinopathy

**Pooling:****Neurosensory detachment**

- Central serous chorioretinopathy
- Optic nerve pit
- Best disease

**Subretinal neovascularization****Retinal pigment epithelium detachment**

- Serous
- Fibrovascular

**Staining**

- Staphyloma
- Disc
- Sclera
- Chorioretinal scar

defects are more difficult to visualize because the native RPE prevents adequate visualization of the choroidal circulation. In general, occlusive diseases that involve isolated, larger choroidal vessels manifest as sectoral, wedge-shaped areas of hypofluorescence. Systemic diseases, including malignant hypertension, toxemia of pregnancy, giant cell arteritis, and lupus choroidopathy, produce zones of hypofluorescence secondary to focal choroidal nonperfusion. Vascular filling defects of the optic nerve head may be noted by fluorescein angiography. Ischemic optic neuropathy manifests as sectoral or complete optic disc hypofluorescence, whereas other atrophic or hereditary anomalies of the optic nerve head have diffuse hypofluorescence.

- **Hyperfluorescence:** Hyperfluorescence is defined as an abnormal presence of fluorescence or an increase in normal fluorescence in the FA. It can be secondary to increased transmission of choroidal fluorescence caused by a window defect created by an area with a decreased or absent RPE that allows a clear view of the underlying choroidal fluorescence (Fig. 6.6.6). The most frequent cause of hyperfluorescence is *leakage* of dye from the intravascular space into the extravascular space. In this case a localized, diffuse hyperfluorescent spot increases in both size and intensity as the study progresses (Fig. 6.6.7). When the dye leaks into an anatomical space (cysts, subretinal space, sub-RPE space) it is called *pooling*. In this case, the boundaries of the hyperfluorescence are more defined, and the speed of appearance depends mostly on the cause (Fig. 6.6.8). Finally, *staining* refers to the deposition of dye within involved tissue and occurs in both normal (optic nerve and sclera) and pathological states (drusen, disciform scars).

**INDOCYANINE GREEN ANGIOGRAPHY****Introduction**

Currently there are two commercially available types of imaging systems for indocyanine green angiography (ICGA): modified fundus cameras (which utilize continuous illumination from a halogen bulb and periodic xenon lamp flashes), and scanning laser ophthalmoscope (SLO)-based systems, which use a focused laser beam to sweep the retina, allowing continuous image acquisition (20–30 images per second).<sup>25</sup>

**Fig. 6.6.4 Blockage.** Fluorescein angiography (FA) image from a patient with idiopathic macular telangiectasia. In this late-phase angiogram, intraretinal pigment plaques are blocking (arrow) the background choroidal fluorescence. Note the significant leakage from the telangiectatic vessels worse temporally as well as staining of the scleral crescent around the optic nerve. (Courtesy Michael Bono, CRA, COT Rocky Mountains Lions Eye Institute, Denver, CO.)

**Fig. 6.6.5 Vascular Filling Defect.** Ultra-wide field fluorescein angiography (FA) image of an inferior hemiretinal vein occlusion in the late phase. There are areas of significant nonperfusion with a large area noted temporal macula (arrow). Note the blockage from heme, leakage from large and small vessels in the macula and periphery. (Courtesy Hoang Nguyen, COT Rocky Mountains Lions Eye Institute, Denver, CO.)

Although the ICG dye gives off 4% of the fluorescence of SF, its maximal peak of absorption is at 790–805 nm and has a peak emission of 835 nm.<sup>18,19</sup> Both exciting and emitted lights are in the near-infrared spectrum, and this allows deeper penetration through the retina, and the emitted light passes more easily through the RPE, blood, lipids deposits, pigment, and mild opacities (cataracts) to form images.<sup>25</sup> Moreover, because the dye has a significantly greater molecular weight, and a greater proportion of molecules remain bound to proteins in the bloodstream, the ICG dye normally remains within the fenestrated walls of the choriocapillaris, unlike SF which leaks freely from these vessels. This property makes ICGA an ideal technique for portraying the anatomy and hemodynamics of the choroid (Fig. 6.6.9).<sup>3</sup>

**Fig. 6.6.6 Window Defect.** Fluorescein angiography (FA) image from a patient with an advanced case of Stargardt disease. The picture shows increasing fluorescence caused by atrophy, noted since the early phases of the angiogram. (Courtesy Valentina Franco-Cardenas, MD: International Retina Fellow, University of California Los Angeles (UCLA).)

## Properties of Indocyanine Green

ICG (benzoindotricarbocyanin) is an amphiphilic tricarbocyanine dye with a molecular weight of 775 kDa.<sup>26</sup> Because of its ability to form aggregates, the ICG lyophilisate has to be dissolved in water for injection. In the bloodstream, the dye is rapidly bound to proteins (98%), especially to albumin, globulins, and lipoproteins, thus remaining longer in large blood vessels and having a lesser tendency to diffuse into the interstitial space.<sup>10</sup> The dye has been approved by the U.S. Food and Drug Administration for use in cardiac, hepatic, and ophthalmic studies.<sup>9</sup> ICG is solely metabolized by the liver through a specific carrier-mediated transport system and excreted in the biliary system. This explains the rapid elimination of the dye from the circulation after an intravenous injection.<sup>26</sup> The dye has a plasma half-life of 2–4 minutes.

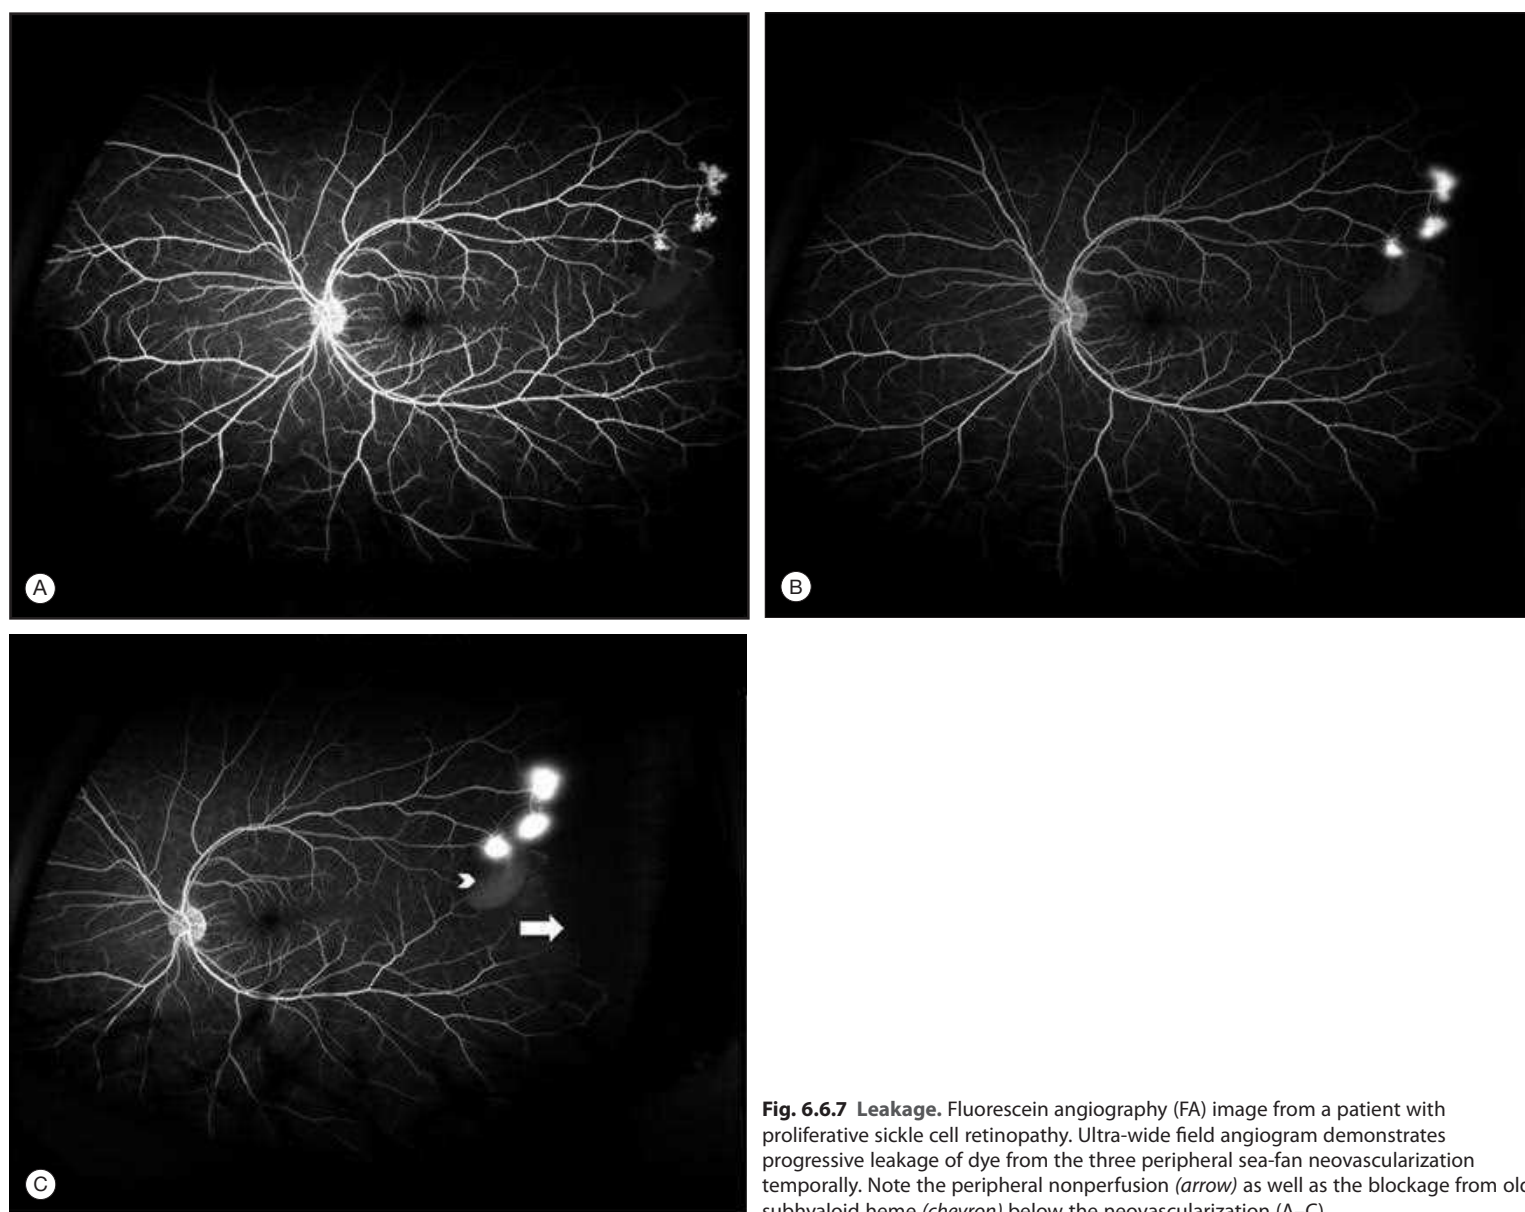

## Procedure

Pharmacological mydriasis is usually required with most systems. The infusion technique is similar to FA, as described above.

The dosage of ICG can vary from 20–50 mg of dye dissolved in 2–4 mL of aqueous solvent. The preferred technique is to slowly inject 25 mg of ICG dye in 5 mL of water. A higher dosage typically results in a larger degree of hyperfluorescence and thereby changes excitation. If both FA and ICGA are performed sequentially, an intravenous catheter may be placed to avoid multiple needlesticks.<sup>18</sup>

Excitation illumination should be at a maximum, with a video gain of +6 dB. Approximately 10 images are acquired over the initial 30 seconds, starting immediately after injection. The video gain and excitation illumination levels should not be changed during the transit phase unless image bloom occurs (an increased fluorescence that obscures images). If this happens, the excitation level is reduced. The best images are retained, and ideally, the transit of ICG through the choroidal vasculature is captured again every 15 seconds. Late images at 5, 10, 15, 20, and 40 minutes after injection also are obtained. Alteration of the excitation level can be increased during the late phase of ICGA if signal intensity is reduced. During the very late stages, both excitation and video gain can be increased; however, a concomitant reduction in detail results.

**Fig. 6.6.7 Leakage.** Fluorescein angiography (FA) image from a patient with proliferative sickle cell retinopathy. Ultra-wide field angiogram demonstrates progressive leakage of dye from the three peripheral sea-fan neovascularization temporally. Note the peripheral nonperfusion (*arrow*) as well as the blockage from old subhyaloid heme (*chevron*) below the neovascularization (A–C).

## Complications

Mild adverse reactions, such as nausea, vomiting, sneezing, and transient itching, occur in 0.15% of cases.<sup>5</sup> Moderate adverse reactions, such as urticarial, syncope, fainting, and pyrexia, may also occur. Severe adverse reactions, such as hypotension, shock, anaphylaxis, and death, have also been reported and occur in equal incidence following ICG and FA (1:1900).<sup>5</sup>

ICG is currently available in several pharmaceutical preparations. Because some of the manufacturing process adds iodine to allow crystallization of the molecule ( $\approx 5\%$  of commercial ICG dyes), crossover allergy to iodine can occur in patients with seafood allergies (shellfish).<sup>9,26</sup> Current contraindications to ICGA include prior anaphylactic reaction to ICG dye or contrast agents that contain iodine, hepatic insufficiency, uremia, and pregnancy. Patients undergoing hemodialysis are also at increased risk of complications from ICG.<sup>9,18</sup>

When local extravasation of the ICG occurs, minimal damage is observed, in contrast to SF, which may cause severe tissue necrosis.

## Interpretation of Results

In the *early phase* of the test, 2 seconds after ICG injection, filling of both the choroidal arteries and choriocapillaris, with early filling of the choroidal veins, occurs. The retinal blood vessels are still dark along with the choroidal “watershed zone” around the optic nerve head. Then, 3–5 seconds after ICG injection, the larger choroidal veins begin to fill and fluoresce along with the retinal arteries as the dye flows. Later, at 6 seconds to 3 minutes, the outer-shed zone is now filled, but the choroidal arteries and large choroidal veins begin to fade (Fig. 6.6.10).<sup>18</sup>

The *middle phase* occurs 3–15 minutes after ICG injection. It is marked by continuous fading of the choroidal and retinal vessels. The *late phase* occurs 15–60 minutes after ICG injections. It demonstrates staining of the extrachoroidal tissue, giving the choroidal vasculature the illusion of hypocyanescence, compared with the background tissue. No retinal vessels are seen during this phase.<sup>18</sup>

Abnormal areas on an ICGA are interpreted as in FA. There can be either *hypo-* or *hypercyanescence*. Hypocyanescence can be attributed to blockage (by blood, serous fluid, pigment, or exudates); impaired choroidal perfusion, either by blocked blood flows on a given area or by loss of choroidal vasculature tissue (acute posterior multifocal placoid pigment epitheliopathy). Hypercyanescence can be caused by a lack of overlying tissue (RPE dropout, lacquer cracks), leakage from retinal or choroidal blood vessels (producing subsequent staining of surrounding tissue), or leakage from abnormal blood vessels (CNV, polypoidal vasculopathy). The terms *hot spots* and *plaques* are used to define areas of intense hypercyanescence during the middle to late phases of the ICGA. *Hot spots* are defined as  $<1$  disc diameter (DD) in size. Hot spots have been attributed to one of three etiologies: polypoidal choroidal neovascularization, retinal angiomatous proliferation, or occult choroidal neovascularization (Fig. 6.6.11). *Plaques*, which are more common, are larger ( $>1$  DD), more amorphous, and reveal less obvious leakage. Combined lesions, which have characteristics of both hot spots and plaques, can also occur.<sup>18,27,28</sup>

*Wide and ultra-wide angle of view:* Wide-field ICGA allows for up to  $160^\circ$  field of view and ultra-wide angiography reaches  $200^\circ$  field of view.<sup>29,30</sup> Peripheral changes are common on ultra-wide field ICGA in many ophthalmic conditions, including, but not limited to, central serous chorioretinopathy, AMD, polypoidal choroidopathy, and myopic degeneration.

**Fig. 6.6.8 Pooling.** Color picture and fluorescein angiography (FA) sequence from a patient with central serous chorioretinopathy. (A) & (C), Small arrowheads delineate an area of neurosensory detachment of the macula with pooling of the dye in the late phase of the study. (B) & (C), Large white arrows indicate areas of retinal pigment epithelium leakage of fluorescein. (Courtesy Valentina Franco-Cardenas, MD: International Retina Fellow, University of California Los Angeles [UCLA].)

**Fig. 6.6.9** Indocyanine green angiography (ICGA) image from a patient with severe atrophy of the retinal pigment epithelium (RPE), in which the choriocapillaris, as well as medium and large choroidal vessels, can be observed. **Fig. 6.6.10** Final stage of the early phase of a normal indocyanine green angiography (ICGA) (at 90 seconds of the study), where the retinal and large choroidal vessels are clearly visible. (Courtesy Jans Fromow-Guerra, MD: Associate Professor. Asociación para Evitar la Ceguera en México, IAP. México DF.)

**Fig. 6.6.11** Fluorescein angiography (FA) and indocyanine green angiography (ICGA) images from a patient with idiopathic polypoidal choroidal vasculopathy and hemorrhagic pigment epithelial detachment. (A) FA with a large hemorrhagic pigment epithelial detachment in the temporal macula (*arrow*) showing blockage and RPE mottling in the periphery. (B) ICGA demonstrates characteristic saccular dilations of the choroidal vasculature just temporal to the disc (*arrow*). The vortex ampullae are also highlighted (*chevron*).

Uveitic (infectious and noninfectious) peripheral changes, including, but not limited to, posterior uveitis, birdshot chorioretinopathy, acute zonal occult outer retinopathy, systemic lupus erythematosus, and sarcoidosis, were also identified.<sup>31,32</sup>

## FUNDUS AUTOFLUORESCENCE

Fundus autofluorescence (FAF) is a noninvasive imaging modality that works by using autofluorescent molecules called *fluorophores* (found in lipofuscin in RPE cells) to provide diagnostic and prognostic information for retinal diseases (Fig. 6.6.12).<sup>33</sup> Camera systems include fundus camera, fundus spectrophotometry, CSLO, and ultra-wide field. FAF is now used widely for various pathologies, including, but not limited to, evaluating AMD, macular dystrophies, retinitis pigmentosa, white dot syndromes, retinal drug toxicities.<sup>34</sup> FAF provides accurate clinical correlation, which has been confirmed by microperimetry and visual field testing. Areas of decreased FAF demonstrates absolute scotomas, whereas increased FAF shows no visible correlate but may be a sign of future cell loss.<sup>34</sup>

**Fig. 6.6.12** Widefield Optos photo (A) and corresponding fundus autofluorescence (B) from a patient with paracentral retinitis pigmentosa. Note the “bull’s eye” maculopathy centrally, hypoautofluorescence in areas of pigment clumping, and mottled hyperautofluorescence seen in a ring around the macula and optic nerve, corresponding to RPE changes noted on the Optos fundus photo.

## ACKNOWLEDGMENTS

The authors thank Valentina Franco-Cardenas, MD, from the University of California Los Angeles (UCLA), and Jans Fromow-Guerra, MD, from APEC, for their assistance with the images in the chapter.

# Optical Coherence Tomography in Retinal Imaging

## 6.7

Arthi Venkat, Miriam Englander, David Xu, Peter K. Kaiser

**Definition:** Optical coherence tomography (OCT) is a noninvasive imaging technique based on the principle of optical reflectometry light, which enables precise anatomical examination of ocular structures.

### Key Features

- High-resolution evaluation of tissue pathology at the cellular level, achieving axial resolution of up to 2–3  $\mu\text{m}$  in tissue.
- Direct correspondence to the histological appearance of the retina, cornea, and optic nerve in health and disease.
- Critical tool in the diagnosis and monitoring of ocular disease involving the retina, choroid, optic nerve, and anterior segment.

### Associated Features

- Easy to use, noninvasive, reproducible, safe.
- Obtainable through most media opacities, including vitreous hemorrhage, cataract, and silicone oil.
- Recent advances allow for a dramatic improvement in the cross-sectional image resolution with improved acquisition speed.
- Helpful in the interpretation of pathologies in all layers of the retina as well as the vitreous–retinal interface.
- Also used for the detection and monitoring of optic nerve, glaucoma, and anterior chamber pathology.

## INTRODUCTION

Optical coherence tomography (OCT) is a noninvasive imaging technique that allows for the examination of ocular structures. This technique utilizes light waves to create the image in a manner similar to ultrasonography, except that reflected light, rather than sound, is used to create the image. Low-coherence light is scanned across the tissue and focused with an internal lens on the ocular structure of interest. A second beam internal to the OCT unit is used as a reference, and a signal is formed by measuring the alteration of the reference beam and comparing this with the reflected beam. The interface between different ocular tissues can be determined by changes in reflective properties between the tissues. Detection of these beams is based on time-domain or spectral-domain protocols.<sup>1</sup>

The use of light allows for high resolution and evaluation of tissue pathology at the cellular level, achieving resolution of 2–3  $\mu\text{m}$ . Other advantages include ease of use, reproducibility, noninvasiveness, safety, and repeatability. In addition, OCT can image through most media opacities, including vitreous hemorrhage, cataract, and silicone oil.

## OCT TECHNOLOGY PLATFORMS

### Time-Domain OCT

In time-domain (TD)-OCT, an individual A-scan is acquired by varying the length of the reference arm in an interferometer such that the scanned length of the reference arm corresponds to the A-scan length. The image is then constructed by using a false color scale that represents the quantified amount of backscattered light, with brighter colors representing high reflectivity and darker colors representing little or no reflectivity. The main

limitations in the clinical use of TD-OCT are the limited resolution and slow acquisition.<sup>2</sup>

### Spectral-Domain OCT

In spectral-domain (SD) or Fourier-domain OCT, the light composing the interference spectrum of echo time delays is measured simultaneously by a spectrometer and a high-speed, charge-coupled device, which allows information of the full-depth scan to be acquired within a single exposure. The interference spectrum is made up of oscillations with frequencies that are proportional to the echo time delay. By calculating the Fourier transform, the machine calculates the axial scan measurements without adjusting the reference mirror. This results in improved sensitivity and image acquisition speed compared with TD-OCT. As a result, SD-OCT is several orders of magnitude more sensitive than TD-OCT.<sup>2</sup> SD-OCT's higher acquisition speeds allow for a shift from two-dimensional to three-dimensional images of ocular anatomy.

### Multifunctional OCT

Functional extensions to OCT add to the clinical potential of this technology. Polarization-sensitive OCT (PS-OCT) provides intrinsic, tissue-specific contrast of birefringent (e.g., retinal nerve fiber layer [RNFL]) and depolarizing (e.g., retinal pigment epithelium [RPE]) tissue with the use of circular or otherwise polarized light. This allows PS-OCT to be useful in glaucoma diagnosis and for the diagnosis of RPE disturbances associated with some diseases, such as age-related macular degeneration (AMD).<sup>3,4</sup>

Doppler tomography enables depth-resolved imaging of flow by observing differences in phase between successive depth scans. This technology provides valuable information about blood flow patterns in the retina and choroid, allowing absolute quantification of flow within retinal vessels. Ultimately, this adjunct of OCT could potentially reduce the need for fluorescein angiography.<sup>5</sup>

### Time-Encoded Frequency-Domain OCT (Swept-Source OCT)

Swept-source OCT, a variation on Fourier-domain OCT, sweeps the frequency of a narrow band continuous wave light source and collects the time-dependent interference signal. Here, the advantage lies in high signal to noise ratio detection technology, achieving very small instantaneous bandwidths at high frequencies (20–200 kHz). This dramatically increases acquisition speed and scan depth. Drawbacks include nonlinearities in the wavelength, especially at high scanning frequencies, and high sensitivity to movements of the scanning target.<sup>2</sup>

### High-Speed, Ultra-High-Resolution OCT

Another variation on Fourier-domain OCT, high-speed, ultra-high-resolution OCT (hsUHR-OCT) allows for a dramatic improvement in cross-sectional image resolution and acquisition speed. The axial resolution of hsUHR-OCT is approximately 3.5  $\mu\text{m}$ , compared with the 10  $\mu\text{m}$  resolution in standard OCT. Imaging speeds are approximately 75 times faster than that with standard SD-OCT. The ultra-high resolution enables superior visualization of retinal morphology in a number of retinal abnormalities. hsUHR-OCT further improves visualization by acquiring high-transverse-pixel density, high-definition images.<sup>6–8</sup>

**Fig. 6.7.1 Optical Coherence Tomography (OCT) Images of a Normal Retina.** (A) Conventional OCT. (B) Spectral-domain (SD) OCT. (C) Average of 12 SD-OCT images (SD-OCT with multiple B-scan averaging). Retinal structures visible include the hyperreflective retinal nerve fiber layer (NFL), hyporeflexive inner nuclear layer (INL), hyperreflective outer plexiform layer (OPL), hyporeflexive outer nuclear layer (ONL), hyperreflective lines that correspond to the junction of the inner and outer photoreceptor segment layers (IS/OS), retinal pigment epithelium (RPE)/Bruch's membrane (BM) complex (RPE/BM), external limiting membrane (ELM), inner plexiform layer (IPL), ganglion cell layer (GCL), and choroidal vessels (Ch). Red arrows indicate structures delineated only by single-scan SD-OCT or SD-OCT with multiple B-scan averaging. (From Sakamoto A, Hangai M, Yoshimura N. Spectral-domain optical coherence tomography with multiple B-scan averaging for enhanced imaging of retinal diseases. *Ophthalmology* 2008;115(6):1071–1078.)

**TABLE 6.7.1 Commercially Available OCT Systems**

System (Company)	Axial Resolution ( $\mu\text{m}$ )	A-Scans per Second	Advanced Features
Cirrus HD-OCT5000 (Carl Zeiss Meditec)	5	68 000	Fixation-independent scan adjustment; multilayer en face C-scan visualization; high-resolution anterior segment imaging; drusen and GA mapping; OCT angiography (AngioPlex)
Spectralis HRAOCT (Heidelberg Engineering)	7 (digital 3.5)	42 000	Point-to-point registration with eye tracking; up to six diagnostic methods in one platform with pinpoint registration between imaging devices; wide-field imaging module for OCT and FA/ICGA; OCT angiography
Avanti RTVue XR (Optovue)	5	70 000	14-mm wide-field macular scans with wide-field analysis; drusen and GA mapping; OCT angiography (Angiovue); software for quantitative analysis of OCTA images
3D-OCT 2000 (Topcon)			Capable of exportation to common multimedia devices; able to import time-domain Stratus OCT images
OCT-HS100 (Canon)	3	70 000	10-mm scan length; 10-layer segmentation analysis; multilingual interface; Doppler retinal blood flow analysis capable
SDOCT (Bioptigen)	4	20 000	Handheld head for pediatric patients or animal research; portability facilitates use in an operating room; Doppler retinal blood flow analysis capable
RS-3000 Advance (Nidek)	3	53 000	12-mm scan length option; segmentation analysis of six distinct retinal layers; OCT angiography capable (Angioscan)
DRI-OCT-Triton (Topcon)	5	100,000	Swept Source device; deeper penetration and 12-mm scan length; OCT angiography capable

FA, Fluorescein angiography; GA, geographic atrophy; ICGA, indocyanine green angiography; OCT, optical coherence tomography; SOCT, spectral OCT; SDOCT, spectral-domain OCT.

## Adaptive Optics OCT

The resolution of OCT systems in the axial dimension is set by the coherence properties of the light source. Current light sources can provide axial resolution below 3  $\mu\text{m}$ , which is more than sufficient to resolve the axial dimensions of most retinal cells. However, the lateral resolution is substantially degraded from the diffraction limit by optical aberrations present in the eye. Consequently, most ophthalmic OCT systems are designed to be operated with a lateral resolution in the range of 15–20  $\mu\text{m}$ . Adaptive optics OCT (AO-OCT) measures aberrations by using a wavefront sensor and uses a wavefront corrector to compensate for the measured aberrations. The ability to correct for diffraction from ocular imperfections allows for very high resolution (2–3  $\mu\text{m}$ ), sufficient for resolution of individual cells<sup>6</sup> (Table 6.7.1).

## ANATOMICAL RESULTS

OCT images correspond to the histological appearance of the retina. The highly reflective nerve fiber layer (NFL) is represented by a red signal.

Similarly, the RPE layer, Bruch's membrane, and choriocapillaris are represented by a red signal because of their higher reflectivity. A third red line represents the junction of the inner and outer segments (called *outer segment ellipsoid zone*). Inner cellular layers have lower reflectivity and are represented by yellow, green, and blue colors. The nonreflective vitreous cavity has a black signal, but the posterior hyaloid face can occasionally be seen as an additional reflective layer anterior to the NFL (Fig. 6.7.1).

The choroid is a highly vascular structure with blood flow and thickness varying in relation to the intraocular pressure, perfusion pressure, refractive error, disease state, and age. It is possible to image the choroid with conventional OCT imaging (Fig. 6.7.2).

## IMAGE OPTIMIZATION

OCT measures the intensity of a backscattered optical signal, which represents the optical properties or reflectivity of the target tissue. The tissue reflectivity varies among different structures, allowing for measurements that can be displayed as false or pseudo-color or gray-scale images. The gray scale runs continuously from high signal (white) to no signal (black),

**Fig. 6.7.2 Comparative Choroidal Imaging With Optical Coherence Tomography (OCT) Sections Through the Fovea Obtained With Various OCT Instruments.** (Top) Heidelberg Spectralis spectral-domain (SD)-OCT using enhanced depth imaging to obtain more choroidal details, including better visualization of the hyporeflective line indicating the edge of the choroid. (Bottom) Cirrus SD-OCT image in which choroidal details are visible with oversampling.

and images can contain up to 256 shades of gray corresponding to the optical reflectivity of the various tissue interfaces. The standard color scale uses a modified continuous rainbow spectrum in which darker colors, such as blue and black, represent regions of minimal or no optical reflectivity and lighter colors, such as red and white, represent a relatively high reflectivity, as described in the Anatomical Results section above.<sup>9</sup>

Studies have shown that compared with the color images, the gray-scale images are easier to interpret and are more informative because of their improved ability to visualize subtle retinal structures, such as photoreceptor inner and outer segment junction (IS/OS), and subtle pathologies, such as thin epiretinal membranes (ERMs).<sup>10</sup>

Another method to improve image quality is to average multiple OCT scans. Frames with the least amount of motion artifacts are chosen. These frames are then averaged. Each pixel value is calculated as an average intensity from all frames, to create one frame. On average, 50 frames are used to create one image.<sup>11</sup>

## OCT IMAGE INTERPRETATION

### Preretinal

The use of OCT has facilitated the diagnosis and description of diseases involving the vitreoretinal interface, including vitreomacular traction syndrome, ERMs, macular holes, and schisis.

#### Posterior Vitreous Detachment

The vitreous in a healthy eye is optically clear. When the vitreous is completely attached, the vitreoretinal interfaces can be detected by the marked change in reflectivity between the vitreous and the internal limiting membrane (Fig. 6.7.3).

#### Vitreomacular Traction

Vitreomacular traction (VMT) is a complication of anomalous partial posterior vitreous detachment (PVD), where the vitreous is separated from the retina throughout the peripheral fundus but remains adherent in a broad region encompassing the macula and/or the optic nerve. A subtle variant demonstrates a localized perifoveal vitreous detachment with a small, focal vitreofoveolar adhesion resulting in an anterior–posterior tractional force that may lead to retinal distortion, cystoid macular edema (CME), or even a macular hole. Several OCT studies have documented that surgical or pharmacological separation of the vitreofoveal adhesion promotes the resolution of macular thickening, usually with improvement in visual acuity in patients with vision loss caused by vitreomacular traction<sup>12</sup> (Fig. 6.7.4).

#### Epiretinal Membrane

An ERM is a result of proliferation of abnormal tissue on the surface of the retina. It is semitranslucent and proliferates on the surface of the internal limiting membrane. ERM has been found to consist of glial cells, RPE cells, macrophages, fibrocytes, and collagen fibers.<sup>13</sup>

On OCT, the ERM appears as a highly reflective thick membrane on the surface of the retina. The strength of the reflection can differentiate it from the posterior hyaloid, which appears as a minimally reflective signal<sup>12</sup> (Fig. 6.7.5).

### Macular Holes

OCT has become the gold standard in diagnosing and monitoring macular holes. OCT technology has been instrumental in the classification of macular hole development, following the sequence of events from anteroposterior vitreofoveal traction to full-thickness macular hole (FTMH)<sup>14–16</sup> (Fig. 6.7.6).

### Lamellar Holes

Lamellar holes are believed to be in the spectrum of macular hole disease but, at least in some eyes, represent an aborted process. In these eyes, OCT imaging shows an irregular, thinned foveal floor with split foveal edges and near-normal thickness of the perifoveal retina (Fig. 6.7.7). OCT images show intact photoreceptors posterior to the area of dehiscence, in contrast to a full macular hole.

### Pseudo-Hole

A macular pseudo-hole is a clinical diagnosis given to an eye with the appearance of a full-thickness defect, but an OCT image that proves an alternative diagnosis. OCT images can readily distinguish between macular pseudo-hole and an FTMH.<sup>17</sup> As with lamellar holes, OCT shows an intact photoreceptor layer. Foveal pseudocyst has also been described as an early stage in the development of macular holes. In these cases, the posterior hyaloid is partially detached over the posterior pole but is still adherent to the fovea, causing a biconvex appearance.<sup>18</sup>

### Intraretinal

#### Macular Edema

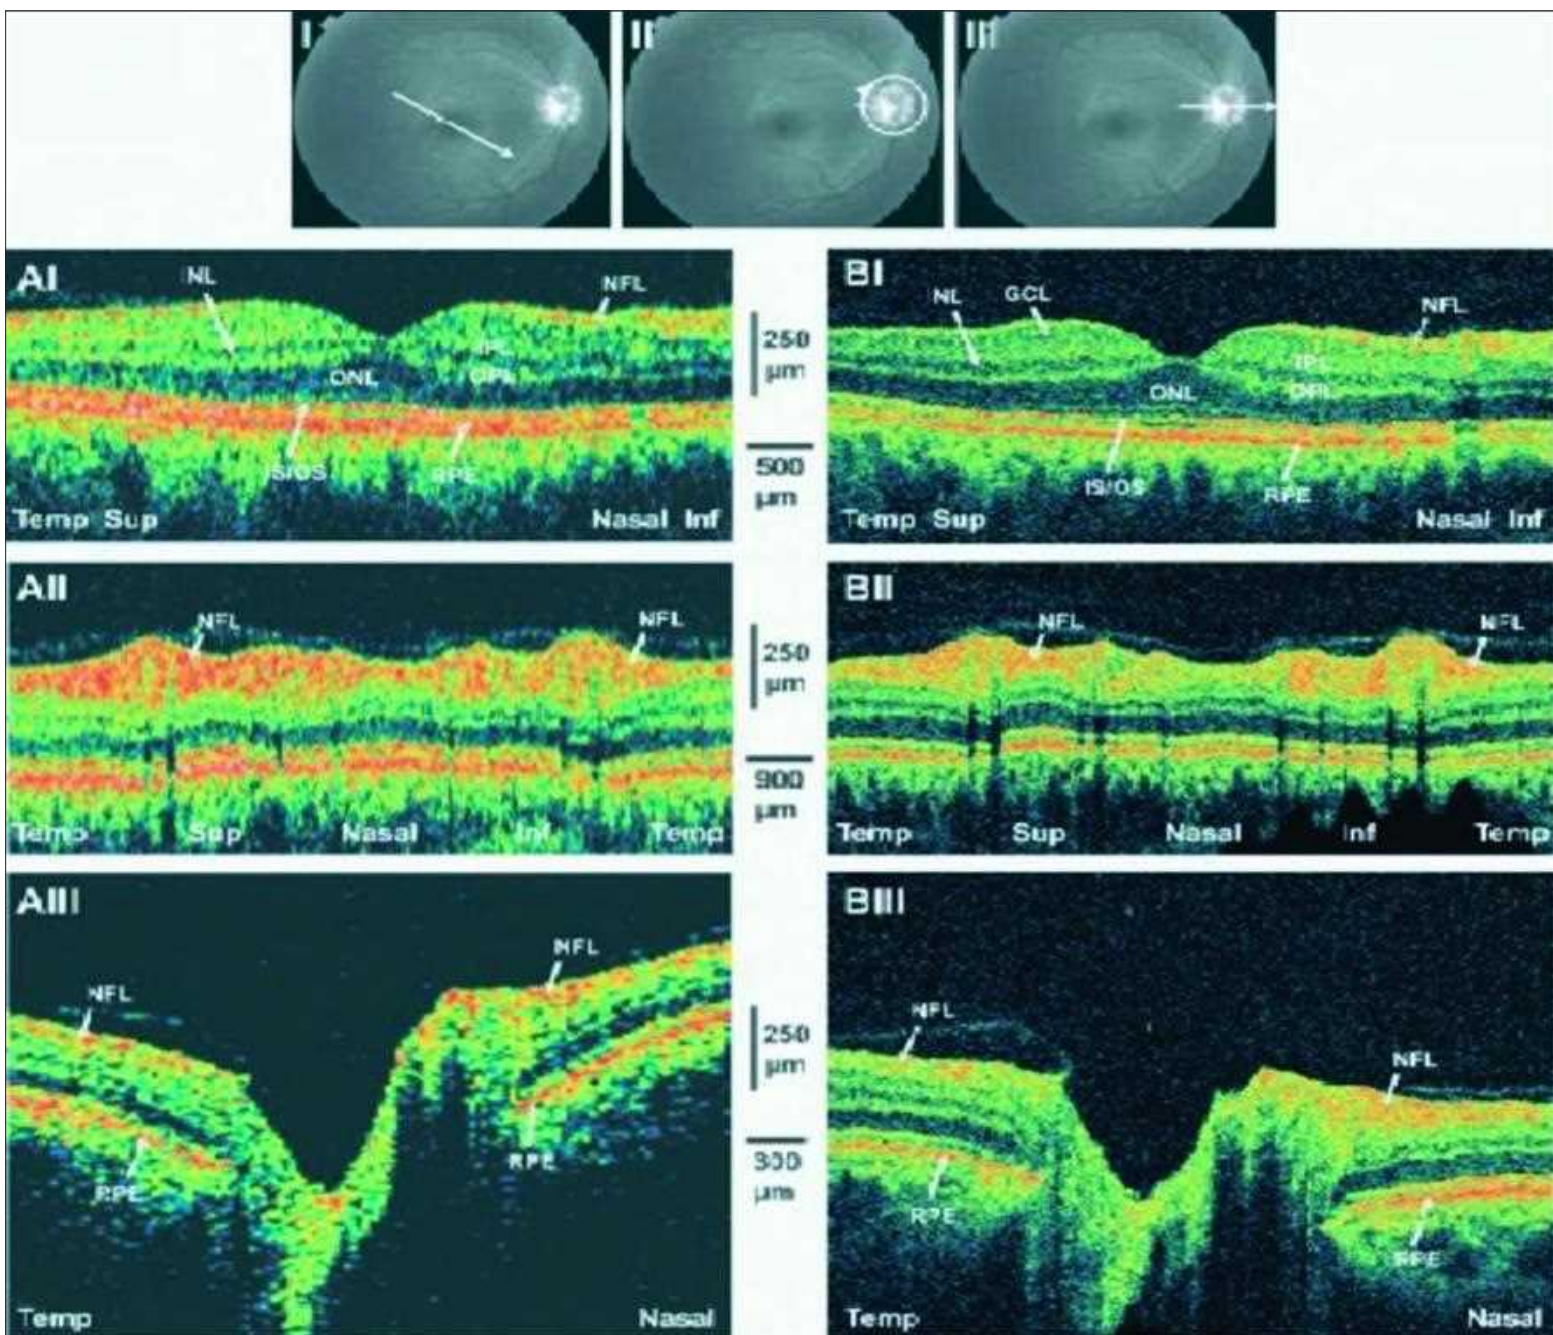

OCT has been shown to be able to detect subtle irregularities and has become essential for monitoring the pre- and postoperative courses of macular edema. Moreover, OCT can aid in differentiating the cause of the edema by identifying cystic spaces in CME or by visualizing the posterior hyaloid in cases of VMT. The advantage of OCT for the assessment of macular edema is its accuracy and reproducibility. In addition, retinal thickness more accurately correlates with visual acuity compared with the degree of fluorescein leakage on fluorescein angiography (FA).<sup>19</sup>

#### Irvine–Gass Syndrome: Cystoid Macular Edema After Cataract Surgery

Approximately 20% of the patients who undergo uncomplicated phacoemulsification or extracapsular extraction develop CME, which can be detected on FA. Macular edema after cataract surgery begins in the inner nuclear layer in the perifoveal area. The central cysts tend to expand to the entire thickness of the retina to the IS/OS junction (Fig. 6.7.8).

### Retinal Exudates

Exudates in the retina are the result of leakage of fluid and lipoproteins as a result of increased vascular permeability. Resorption of the fluid results in the precipitation of lipids, most commonly in the outer plexiform layer of the retina but can also be seen in the subretinal space.<sup>20</sup> These exudates can be seen in any condition that causes chronic vascular leakage, including, but not limited to, diabetes, hypertension, Coats' disease, choroidal neovascularization, retinal macroaneurysm, and capillary hemangioma.

**Fig. 6.7.3** Stratus time-domain (TD)-OCT (A) and prototype, ultra-high-resolution optical coherence tomography (UHR-OCT) (B) scans of a normal subject. I, Macular linear scans, whose orientations are depicted in the upper image. II, Peripapillary circular scans. III, Optic nerve head (ONH) linear scans. Inf, inferior; INL, internal nuclear layer; IS/OS, inner segment/outer segment; NFL, nerve fiber layer; ONL, outer nuclear layer; OPL, outer plexiform layer; RPE, retinal pigment epithelium; Sup, superior; Temp, temporal. (From Wollstein G, Paunescu LA, Ko TH, et al. Ultrahigh-resolution optical coherence tomography in glaucoma. *Ophthalmology* 2005;112(2):229–37.)

**Fig. 6.7.4** Vitreomacular Traction (VMT). Vitreofoveolar traction resulting in an anterior–posterior tractional force leading to cystic macular edema.

On OCT, these exudative lesions appear as highly reflective areas that cause a shadowing effect of the underlying retinal layers (Fig. 6.7.9).

## Subretinal

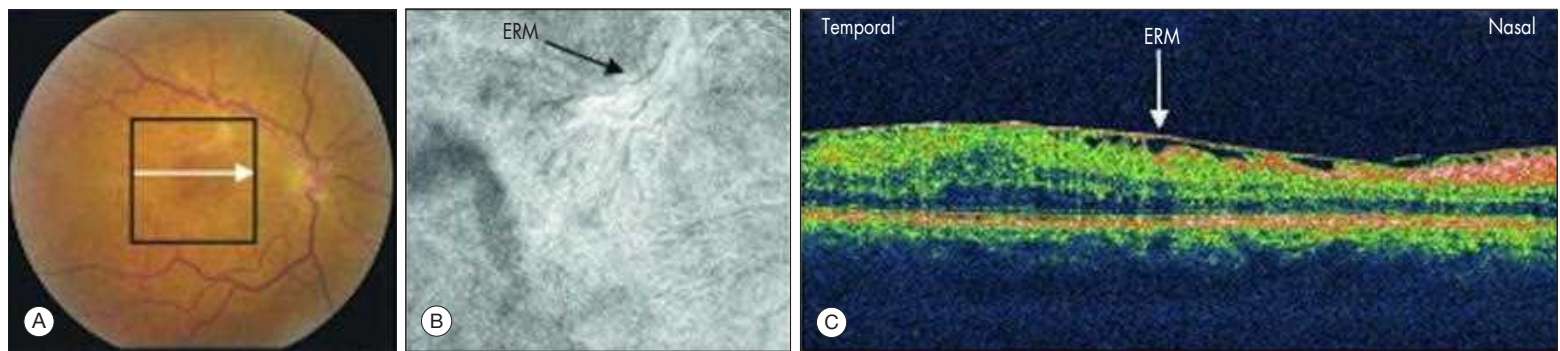

### Subretinal Fluid

Subretinal fluid causes a separation of the neurosensory retina from the underlying RPE. On OCT, an optically empty space can be seen between the detached retina and the RPE. This cavity is filled with serous fluid. Causes of subretinal fluid include retinal detachment, central serous chorioretinopathy, and choroidal neovascular membrane.

### Pigment Epithelial Detachment

A retinal pigment epithelial detachment (PED) is formed by the separation of the RPE from Bruch's membrane because of the presence of sub-RPE fluid, blood, fibrovascular membrane, or drusenoid material (Fig. 6.7.10). The various forms of PEDs differ in their underlying pathogenesis, OCT appearance, and response to therapy.

**Fig. 6.7.5** (A) Fundus photograph showing an epiretinal membrane (ERM) on the macula. (B) Reconstructed fundus image corresponding to black box on fundus photograph. (C) Spectral-domain optical coherence tomography image showing the ERM. (From Legarreta JE, Gregori G, Knighton RW, Punjabi OS, Lalwani GA, Puliafito CA. **Fig. 6.7.9** Highly reflective hard exudates accumulated in the inner portion of the neurosensory retina. A faint shadow of low reflectivity is behind the hard exudates in the outer retinal layers and retinal pigment epithelium.

**Fig. 6.7.10** Optical coherence tomography (OCT) image through drusenoid pigment epithelial detachment (PED).

### RPE Tear

RPE tear is a potentially visually devastating complication of PED. The tear is caused by contraction and retraction of the elevated PED, leading to absence of RPE underneath the neurosensory retina. Tears can be seen after treatments, including laser photocoagulation, photodynamic therapy, and anti-vascular endothelial growth factor therapy. Characteristic findings on OCT include focal interruption of the RPE signal, hyperreflectivity of the retracted and rolled RPE, and increased reflectivity of the bare choroid as a result of increased signal penetration in the absence of overlying RPE<sup>21,22</sup> (Fig. 6.7.11).

**Fig. 6.7.11** Optical coherence tomography (OCT) image of a retinal pigment epithelium (RPE) tear.

## Choroidal Pathology

Cross-sectional imaging of the choroid is challenging because of light scattering and absorption. One method using SD-OCT is enhanced depth imaging (EDI). In EDI, the OCT machine is moved closer to the eye, thereby placing the peak sensitivity curve closer to the region of the choroid. Averaging approximately 100 images together improves the image resolution. The image is then reinverted to correlate to the anatomical orientation of the tissue. Averaging images is possible with instruments that are capable of eye tracking.<sup>23</sup>

### Choroidal Neovascularization

Choroidal neovascularization (CNV) can complicate many ocular conditions, including AMD, uveitis, myopia, presumed ocular histoplasmosis, angioid streaks, and choroidal rupture. CNV is subdivided into different subtypes: type 1 (below the RPE), type 2 (above RPE below retina), and type 3 (retinal angiomatous proliferation [RAP]). Choroidal blood vessels invade the sub-RPE (type 1) or subretinal space (type 2) via a break in Bruch's membrane or from an anastomosis with the retinal circulation (type 3). Histologically, these blood vessels lack endothelial tight junctions, which leads to serous fluid leakage.

Advancements in high-resolution three-dimensional OCT suggest that retinal neovascularization alone or concomitant CNV can be present in early RAP. Early lesions present with extensive macular edema and cyst formation as the lesion progresses, the neovascularization extends beneath the retina, and subretinal fluid accumulates. In later stages, serous PED occurs, and CNV becomes evident. At this stage, it is difficult to differentiate between CNV subtypes. Therefore, OCT is useful in the initial stage of type 3 neovascularization to image the vessels and the cystic spaces within the retina. However, once a PED occurs, it is very challenging to assess the sub-RPE changes.<sup>24</sup>

NOTE: Applications of OCT in the fields of glaucoma, cornea, and neuro-ophthalmology are discussed in the other chapters in this text.

## OCT Artifacts

### Time-Domain OCT

Artifacts are commonly encountered with the use of TD-OCT, often related to errors in acquisition or interpretation. Acquisition errors are caused by the speed of obtaining the image and the presence of media opacities or optical aberrations. Because of the relatively long acquisition time, excessive eye movements or poor fixation will degrade the image.

### Spectral-Domain OCT

Compared with TD-OCT, acquisition speed is about 50 times faster with SD-OCT, minimizing motion artifacts. In spite of this, acquisition artifacts can still occur as a result of poor centration of the image or presence of media opacities. In addition, the capability of generating a three-dimensional image of the macula reduces the chances of missing focal lesions. SD-OCT also facilitates acquisition of significantly larger numbers of scans, allowing for higher resolution.

# Optical Coherence Tomography Angiography

6.8

Kyle M. Green, Cullen J. Barnett, Amir H. Kashani

**Definition:** Optical coherence tomography angiography (OCTA) is an imaging modality that uses variation (or decorrelation) in the optical coherence tomography (OCT) signal to detect motion in biological tissues.

### Key Features

- OCTA can noninvasively detect the movement of red blood cells at capillary-level resolution.
- OCTA is particularly useful for detecting regions of impaired perfusion and neovascularization.
- OCTA has been used to evaluate many of the pathological macular changes in retinal vascular diseases, including diabetic retinopathy, retinal vein occlusion, macular telangiectasia, and neovascular age-related macular degeneration.

### INTRODUCTION

Optical coherence tomography (OCT) is a noninvasive imaging method that has been used extensively in the field of ophthalmology since 2002. OCT generates high-resolution cross-sectional images of the retina based on the interference of back-scattered coherent light.<sup>1</sup> Progress in OCT technology has facilitated new OCT-based imaging methods, such as polarization-sensitive OCT,<sup>2</sup> spectroscopic OCT,<sup>3</sup> phase-sensitive OCT,<sup>4-6</sup> and spectral-domain (SD) OCT angiography (OCTA).<sup>7</sup> OCTA is a functional extension of OCT and is being used increasingly to detect microvascular changes in many retinal diseases since approval by the U.S. Food and Drug Administration in 2016. We will briefly review the biological basis of OCTA imaging, highlight the various methods of generating OCTA images, and discuss the strengths and limitations of this novel method.

### BIOLOGICAL BASIS OF OCTA

OCTA is based on the variation in OCT signal caused by moving particles, such as red blood cells (RBCs), in contrast to stationary surrounding neurosensory tissue. This variability is relatively analogous to the Doppler shift that moving particles impose on reflected light. Although there are several different methods of performing OCTA imaging (Table 6.8.1), all of these methods differentiate moving particles from static retinal tissue by comparing multiple (two or more) OCT B-scans performed at the same location.<sup>8</sup> This is in contrast to standard OCT, which performs a single B-scan at each location. Because RBCs are constantly moving, they generate

a unique variation in the intensity and phase of the backscattered OCT signal compared with the nonmoving retinal tissue within each repeated B-scan at the same location. Several methods of analyzing this variance have been developed and can be divided into those that use the phase variance of light, the intensity variance of light, or both phase and intensity (see Table 6.8.1).

OCTA images provide a map of retinal vessels with blood flow detectable on SD-OCTA devices, but do not provide the rate of blood flow at any locations (Fig. 6.8.1). In vitro studies and some in vivo studies suggest that current SD-OCTA devices can detect blood flow in the range of 0.3–3.3 mm/sec.<sup>8</sup> This is approximately the range that has been demonstrated by confocal scanning laser ophthalmoscopy.<sup>9</sup> Flow rates above or below this range may artifactually appear as regions of “nonperfusion.” Also of note, although RBCs are the most mobile component of retinal tissue, any particulate motion can theoretically generate similar motion contrast signal. For example, lipid particulates in solution generate OCTA signals as a result of Brownian motion.<sup>10</sup> Therefore, the possibility of artifactual signal should be considered when interpreting OCTA images.

### OCTA VERSUS DYE-BASED ANGIOGRAPHY METHODS

With the rapid adoption of OCTA, it becomes necessary to determine the appropriate roles of OCTA versus those of fluorescein angiography (FA) and indocyanine green angiography (ICGA). Table 6.8.2 summarizes many of the strengths, limitations, and practical applications of these methods. It is important to recognize that although OCTA and dye-based angiography methods provide somewhat similar en face images, they measure different biological phenomena. Specifically, OCTA is based on light scattering from RBCs and particulate debris, so there is no diffusion of dye on OCTA images. This fundamental difference is illustrated by the absence of “leakage” on OCTA images in subjects who have macular edema on FA. Another illustration of this difference is the variable rate of microaneurysm detection on OCTA in comparison with FA.

Many studies have demonstrated that OCTA does not directly detect hyporeflective pockets of intraretinal fluid as observed on OCT. Nor does OCTA demonstrate the hyperfluorescence that is observed in late phase FA in subjects with diabetic macular edema or cystoid macular edema.<sup>11-14</sup> This is attributed to the notion that fluid within most cystoid spaces does not contain large particles that can backscatter light.<sup>10</sup> In contrast, FA is based on the tissue distribution and fluorescence of dye molecules that leak into cystoid spaces. Although dye leakage highlights cystoid spaces as well as abnormal vessels, such as neovascularization (Fig. 6.8.2), it also tends to obscure potentially relevant details both in pathological cases as well as normal cases. This is because there is still modest dye leakage from normal vessels which increases the background noise in FA and ICGA.<sup>15-17</sup> For example, high background fluorescence can make it appear as though the macula is completely ischemic by obscuring fine capillaries in proliferative diabetic retinopathy, whereas OCTA can clearly demonstrate the persistence of capillaries and visual potential.

Some recent studies have highlighted the significant difference in appearance of microaneurysms on OCTA versus FA,<sup>12</sup> whereas others have shown significant similarities.<sup>13</sup> In some cases, the excellent depth resolution of OCTA images has revealed that lesions consistent with the appearance of microaneurysms on FA are actually small tufts of neovascularization.<sup>14</sup> It has also been demonstrated that, at least in some cases, microaneurysms are not detected as frequently on OCTA as on FA.<sup>12</sup> Even

TABLE 6.8.1 Summary of Optical Coherence Tomography Angiography (OCTA) Methods

**Fig. 6.8.1** Demonstration of various field-of-views in optical coherence tomography angiography (OCTA). (A)  $3 \times 3$  mm, (B)  $6 \times 6$  mm, and (C)  $8 \times 8$  mm field-of-view pseudo-colored OCTA of a normal subject. Red represents superficial retinal layer. Green represents deep retinal layer. Yellow represents regions of overlay. Images are from an AngioPlex device.

when microaneurysms are detected on OCTA, they are usually of different sizes and shapes compared with those on FA. It is likely that the reason for this and the discrepancy among studies is that some microaneurysms are sclerosed or clotted and without blood flow, whereas others are patent or partially patent.<sup>18</sup> Because OCTA only detects the movement of RBCs, sclerosed or clotted microaneurysms will not appear at all on OCTA. In addition, the flow rate of blood within microaneurysms may be outside the detection speed of SD-OCTA devices.<sup>19</sup> Microaneurysms that are partially sclerosed or partially recanalized will also appear much smaller on OCTA than on FA because only the region with RBC flow will be visualized on the former, whereas the whole lesion will stain with dye on FA.

Other considerations for the use of dye-based angiography versus OCTA are their practical limitations and strengths (see Table 6.8.2). These considerations include how each method is performed and the resolution of the images. The most important drawback of any dye-based method is

the possibility of adverse reactions ranging from mild reactions to severe and possibly life-threatening reactions.<sup>16,20,21</sup> An important strength of dye-based imaging methods is that current wide-field systems provide an almost comprehensive assessment of the central and peripheral retina. In addition, ICGA is generally superior in detection of choroidal neovascularization (CNV) compared with current OCTA systems because of the limited penetration of the OCTA signal through the retinal pigment epithelium (RPE). Lastly, compared with OCTA, dye-based angiography has relatively limited resolution. For example, although FA can delineate the foveal avascular zone very well in primates, <40% of the capillaries outside the foveal center are visualized on FA as compared with histology.<sup>22</sup> Mendis et al. showed that FA assessment of capillary density is  $\approx 50\%$  less than histology-based assessments.<sup>15</sup> Specifically, FA cannot resolve the radial peripapillary plexus or the capillaries in the deep retinal layers.<sup>23</sup> In contrast, OCTA clearly and reliably resolves these capillaries in human subjects.<sup>23,24</sup>

TABLE 6.8.2 Strengths and Limitations of Optical Coherence Tomography Angiography (OCTA) Versus Dye-Based Imaging Methods

<sup>a</sup>Limitations column applies to both ICGA and FA.  
CNV, Choroidal neovascularization; IV, intravenous; RPE, retinal pigment epithelium.

**Fig. 6.8.2** Illustration of neovascularization of the disc in a subject with proliferative diabetic retinopathy. (A) Depth-encoded optical coherence tomography angiography (OCTA) image of optic disc with overlying neovascularization in red. In this case, the neovascularization appears red because it is within the same plane or above the plane of the superficial retinal layer. (B) B-scan illustrates the location of the neovascularization above the optic disc. Red = superficial retinal layer; green = deep retinal layer; yellow = overlap. Images are from an AngioPlex device.

One final caveat with regard to OCTA is the potential to misinterpret images because of artifacts.<sup>25</sup> In many cases, the artifacts on OCTA are similar to and derived from artifacts that are observed on standard OCT images. The most common in OCTA images is called a “projection artifact,” where vessels in the superficial retinal layers cast shadows or “projections” on deeper retinal layers, which results in the artifactual appearance of vessels where none exists. This is most clinically relevant in the interpretation of choroidal pathology and CNV. An excellent review of the subject is available,<sup>26</sup> and several methods of removing these artifacts have been developed.<sup>26,27</sup>

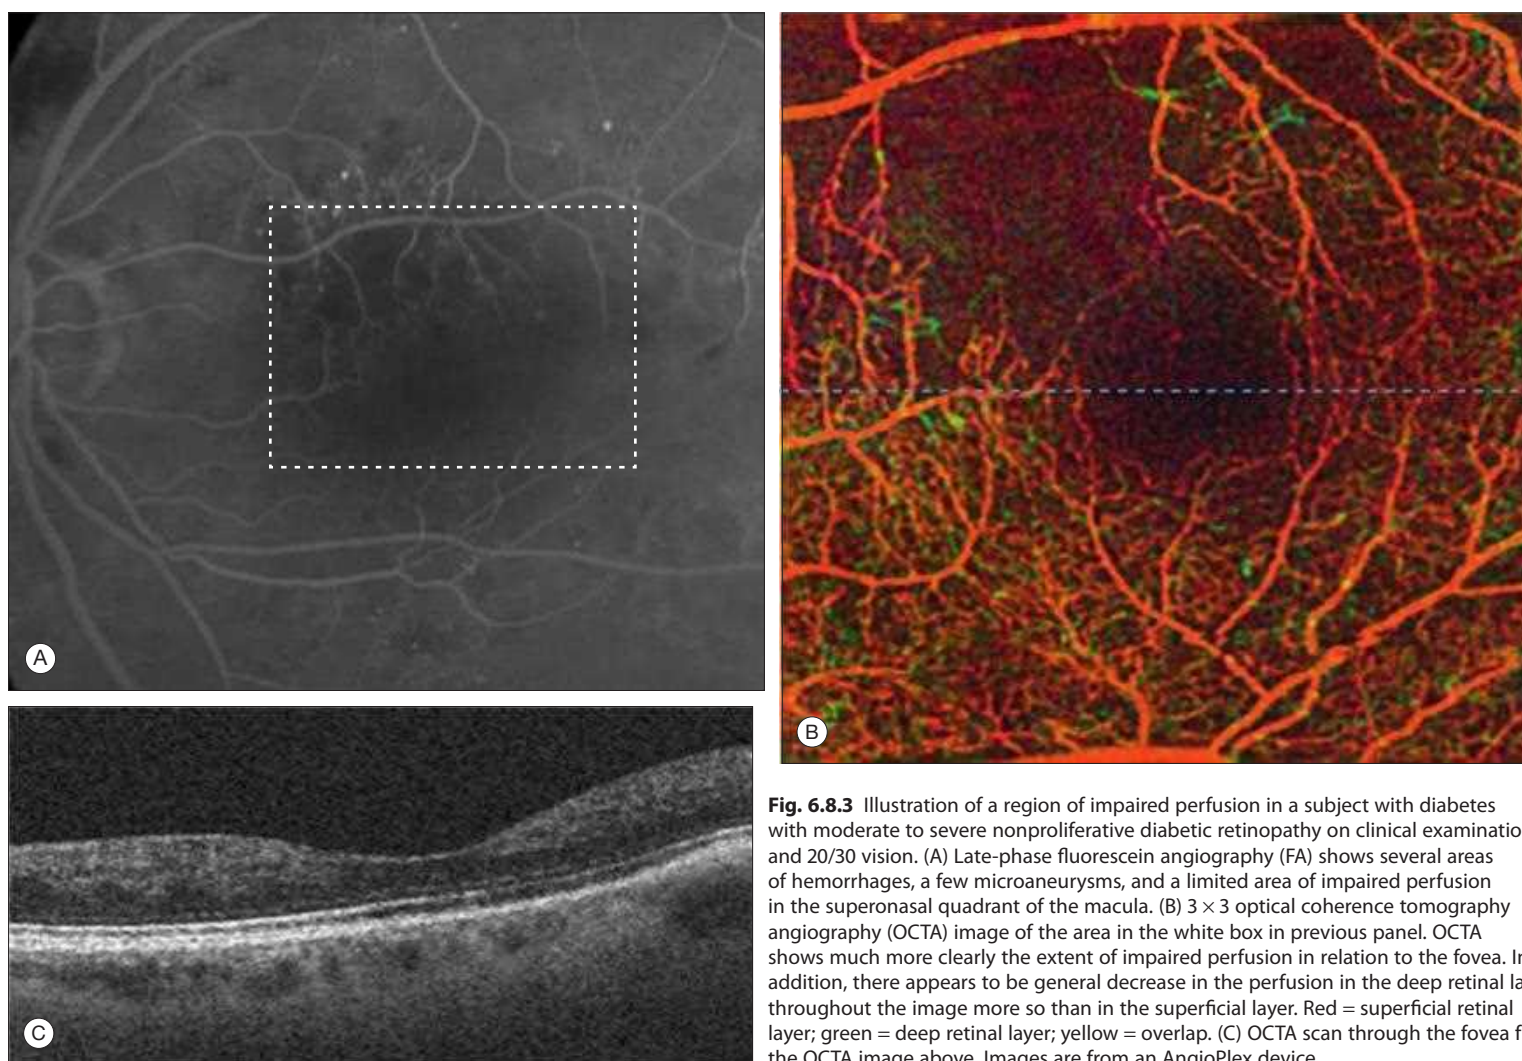

KEY APPLICATIONS OF SD-OCTA

Detection of Impaired Perfusion (or “Nonperfusion”)

In this chapter, we refer to “nonperfusion” as “impaired perfusion.” Because it is very hard to absolutely demonstrate lack of blood flow with

any current imaging method, the term “nonperfusion” is misleading and likely inaccurate in many cases. For both dye-based imaging studies as well as OCTA, there can be very slow blood flow rates that are either obscured by background noise or undetectable. Because of the relatively low resolution of FA, impaired perfusion is likely very severe by the time it is detectable on FA. In contrast, OCTA can reliably resolve individual capillaries with unprecedented depth-resolution in humans.<sup>23,24,26,28</sup> OCTA images demonstrate capillary detail approaching the resolution of histology.<sup>15,23,24,29</sup> This makes OCTA an ideal method for detecting and monitoring regions of impaired perfusion in subjects with retinal vascular disease (Fig. 6.8.3). In addition, OCTA can be repeated many times to obtain the ideal image with essentially no risk to subjects, which is not possible with FA. Therefore, OCTA provides a whole new dimension of depth information regarding the severity of impaired perfusion that is not possible with FA. For example, studies have suggested that impairment of perfusion in the deep retinal layers is more severe in certain diseases, such as paracentral acute maculopathy,<sup>30</sup> diabetic retinopathy,<sup>31</sup> and retinal venous occlusion.<sup>11,32,33</sup> In addition, detection of capillary loss in the macula of patients with diabetes<sup>28,34</sup> and peripapillary capillary plexus of patients with glaucoma<sup>35,36</sup>

**Fig. 6.8.3** Illustration of a region of impaired perfusion in a subject with diabetes with moderate to severe nonproliferative diabetic retinopathy on clinical examination and 20/30 vision. (A) Late-phase fluorescein angiography (FA) shows several areas of hemorrhages, a few microaneurysms, and a limited area of impaired perfusion in the superonasal quadrant of the macula. (B) 3 × 3 optical coherence tomography angiography (OCTA) image of the area in the white box in previous panel. OCTA shows much more clearly the extent of impaired perfusion in relation to the fovea. In addition, there appears to be general decrease in the perfusion in the deep retinal layer throughout the image more so than in the superficial layer. Red = superficial retinal layer; green = deep retinal layer; yellow = overlap. (C) OCTA scan through the fovea from the OCTA image above. Images are from an AngioPlex device.

is now possible before clinical lesions are evident. The clinical relevance of this additional information remains to be determined, but at the least OCTA will allow for detection of impairment in blood flow (ischemia) much earlier than before and help assess the severity of the impairment with far more precision.

### Detection of Choroidal Neovascularization

Many studies have demonstrated that OCTA is useful for detecting and assessing the severity of CNV in several diseases, including neovascular age-related macular degeneration (AMD),<sup>37–39</sup> macular telangiectasia,<sup>40</sup> uveitis,<sup>41</sup> and central serous retinopathy,<sup>42</sup> among others (Fig. 6.8.4). Because OCTA is completely noninvasive and easy to perform in the clinic, it provides an unprecedented opportunity for real-time evaluation of retinal vascular changes. For example, the real-time regression of CNV during antivascular endothelial growth factor therapy has been demonstrated by using OCTA.<sup>43</sup> Although OCTA can detect the presence and extent of CNV above the RPE (type 2), CNV detection for lesions below the RPE may be more challenging because the RPE is highly reflective and can severely attenuate the OCTA signal.<sup>38,44–46</sup> Nevertheless, OCTA imaging of CNV lesions can be useful because it can be performed with higher frequency compared with FA or ICGA. The clinical significance of this has yet to be determined, but it is promising that OCTA is allowing earlier detection of lesions that could progress and cause vision loss.

### Quantification of Vascular Changes

One of the most promising applications of OCTA is objective and quantifiable assessment of capillary level changes in the retina. The fact that OCTA has excellent spatial resolution, poses minimal risk, and is very fast makes it amenable for real-time assessment of capillary level changes in several

retinal diseases. For example, in diabetic retinopathy, several studies have demonstrated that OCTA-based metrics, such as capillary density, correlate with the clinical severity of the disease.<sup>31,47–49</sup> Similar metrics have been demonstrated to correlate with clinical severity of disease in subjects with retinal venous occlusion,<sup>50–53</sup> history of uveitis,<sup>54</sup> and glaucoma.<sup>36,55</sup>

### CONCLUSIONS

In summary, OCTA is rapidly becoming an important tool for the diagnosis and management of retinal vascular diseases. It is clear that OCTA is at least as good as invasive dye studies for assessing the macular complications of retinal diseases, such as diabetic retinopathy, retinal venous occlusion, and some forms of macular degeneration. It is also clear that the excellent depth and lateral resolution of OCTA in general makes it superior to FA, allowing for detection of much milder vascular changes. The main limitation of OCTA in clinical applications is the field of view, but this is rapidly improving as commercial systems adopt larger scan patterns. Therefore dye-based angiography is still necessary for assessment of the peripheral retina. Another major limitation of OCTA is the suboptimal detection of choroidal neovascularization and other pathology found beneath the RPE. It is very likely that emerging swept-source systems with longer wavelengths of coherent light will overcome both of these limitations. For the spectrum of retinal vascular disease that has been managed with invasive dye studies in the past, it is very likely that OCTA will gradually become the dominant modality for both diagnosis and management of macular complications. For diseases in which dye-based angiography had no role, such as glaucoma, OCTA provides a novel tool to assess the peripapillary capillary plexus. Given the speed with which clinical interest around OCTA is evolving, it will not be long before all of these limitations are overcome. OCTA stands to change the practice of ophthalmology in the next decade as profoundly as it has changed it in the last.

**Fig. 6.8.4** Illustration of choroidal neovascularization (CNV) in a subject with neovascular age-related macular degeneration (AMD). (A) OCTA image of choriocapillaris slab demonstrates large caliber and irregularly organized vessels in the CNV complex. (B) B-scan illustrates the boundaries of the OCTA slab shown in the above panel and location of the CNV within the retinal profile. Images are from an AngioPlex device.

# Retinal Electrophysiology

Elias Reichel, Kendra Klein

## 6.9

**Definition:** Objective functional ancillary testing of the retina and/or retinal pigment epithelium (RPE) that records electrical responses based on various stimuli and assists in the diagnosis and management of various retinal diseases, especially inherited retinal dystrophies, autoimmune disorders, inflammations, and medication toxicities.

### Key Features

- Electroretinography (ERG) records the electrical response evoked from the entire retina by a brief flash of light and consists of an *a*-wave, which represents the photoreceptor response, and a *b*-wave, which represents the combined response of the Müller and bipolar cells.
- The multifocal ERG (mfERG) is a record of multiple local ERG responses elicited from the central 40° of the retina.
- Electrooculography (EOG) records the standing electrical potential generated by the RPE.
- The International Society for Clinical Electrophysiology of Vision (ISCEV) provides worldwide standardized clinical protocols for electrophysiological testing, including guidelines for ERG, mfERG, and EOG testing.

### INTRODUCTION

Electrophysiology encompasses several objective examination techniques that measure the function of the retina by measuring action potentials caused by particular patterns of light stimulation within the retina. Clinical electroretinography (ERG) is useful to determine the existence of retinal degenerative conditions caused by hereditary, toxic, metabolic, retinal vascular, or inflammatory etiologies, being particularly valuable in determining the abnormal nature of what clinically appears to be a normal retina. Full-field ERG represents a mass-evoked response of the outer retinal layers, which reflects total retinal function. The multifocal (mf)-ERG represents a cone-generated response of localized retinal function in the central macula, which is useful in establishing the presence of macular dysfunction. Electro-oculography (EOG) represents the standing electrical potential of the entire eye, which reflects the pigment epithelium. These electrophysiological results should be considered in conjunction with those of complete medical and ophthalmic evaluations, including a careful history and laboratory testing, when indicated.<sup>1,2</sup>

### FULL-FIELD ERG

The full-field, or Ganzfeld, ERG measures a mass response generated by cells from the entire retina. Photoreceptors generate the initial negative component, or *a*-wave, whereas Müller cells and bipolar cells are responsible for the later, positive, *b*-wave. Both *a*-wave and *b*-wave are best illustrated in the maximal combined rod-cone response. The ganglion cell layer does not contribute to the ERG. The full-field ERG is useful for establishing generalized loss of rod or cone function, or both. Patients who have focal macular disorders do not have abnormalities of full-field ERG amplitude, nor do patients who have diseases of the inner retina, optic nerve, or cortical conditions.<sup>1,2</sup>

Starting in 1989, the International Society for Clinical Electrophysiology of Vision (ISCEV) has put forth standardized basic ERG protocols to allow comparison across laboratories, and these protocols are periodically updated. The most recent ISCEV standard for full-field clinical ERG includes six protocols, which are named according to the stimulus (flash

strength in candela-seconds per meter squared [ $\text{cd/s/m}^2$ ]) and the adaptation state<sup>3</sup> (Fig. 6.9.1). In preparation, the pupils should be maximally dilated, and the pupil size should be noted before and after the responses are recorded. Prior to recording scotopic electroretinograms, the patient should have 20 minutes of dark adaptation, and prior to recording scotopic electroretinograms, the patient should have 10 minutes of light adaptation. Following dark adaptation, weaker flashes of light stimuli should be presented prior to stronger flashes. Likewise, fluorescein angiography (FA) and fundus photography should be avoided directly prior to testing. Contact electrodes (connected to the positive input) are utilized and include corneal contact lenses, conjunctival conductive fibers, and lower eyelid skin electrodes. The cornea is protected with nonirritating conductive solution, and topical anesthesia is employed, as necessary. Reference electrodes (connected to the negative input) are incorporated either as a contact lens–speculum assembly or as skin electrodes placed near each orbital rim. A separate electrode is used as the common electrode and is attached to the earlobe, mastoid, or forehead. Full-field (Ganzfeld) stimulation is used for uniform retinal illumination with a fixation spot. The maximum flash duration is 5 milliseconds (ms). The flash strength for ERG testing is described in units of  $\text{cd/s/m}^2$ , with a weak flash stimulus strength of 0.010 photopic  $\text{cd/s/m}^2$ , a standard flash stimulus of 3  $\text{cd/s/m}^2$ , and a strong flash stimulus of 10 photopic  $\text{cd/s/m}^2$ . Light adaptation and background luminance are set at 30  $\text{cd/s/m}^2$ . Stimulus and response names are described by the state of light adaptation and the flash strength in photopic  $\text{cd/s/m}^2$ .<sup>3</sup>

Normal values for full-field ERG vary by laboratory, so normal intralaboratory value ranges should be given with every ERG report, and reference values should be adjusted for age. Ocular pigmentation, high refractive errors, and time of recording should be noted.<sup>3</sup>

An electrophysiological response may be affected in both amplitude and/or timing (Fig. 6.9.2). The *a*-wave amplitude is measured from the prestimulus baseline to the *a*-wave trough, and the *b*-wave amplitude is measured from the *a*-wave trough to the *b*-wave peak. Timing includes the peak time (also called *implicit time*, *t*) and is measured from the time of the flash to the peak of the wave of interest (see Fig. 6.9.2, arrows). The amplitude of a flicker ERG is measured from the trough to the peak of a typical wave, and the implicit time is measured from the midpoint of the stimulus to the following peak. With regard to measuring oscillatory potentials, most clinical applications are noting the presence and waveform of the peaks in comparison with reference data.<sup>3</sup>

Full-field ERG can establish loss of retinal function in pathological states, exhibited as alterations in amplitude and timing of the recorded retinal responses when compared with normative responses and assists in diagnosis in clinical scenarios that include unexplained loss of peripheral vision, loss of central vision, and nyctalopia.

When retinal degeneration is suspected, full-field ERG can differentiate between an isolated cone abnormality and a condition that involves both the rods and cones. In addition, full-field ERG can differentiate between stationary forms of night blindness and progressive degenerations. In cone-rod dystrophy, photopic (cone) responses are affected more compared with scotopic (rod) responses; the reverse is true in rod-cone dystrophy. However, as each of these dystrophies progresses, both rods and cones can become affected.<sup>4</sup> In retinitis pigmentosa, for example, the earliest sign of retinal damage is a delayed cone implicit time. As the disease progresses, however, the ERG demonstrates both markedly reduced rod and cone responses to bright flash and a markedly reduced cone response to a 30-hertz (Hz) flicker. Late in the disease course, responses are often non-recordable<sup>5</sup> (Fig. 6.9.3).

Full-field ERG testing can be helpful in diagnosing various systemic conditions that result in loss of retinal function, such as autoimmune retinopathy, vitamin A deficiency, and various drug toxicities.<sup>6</sup> Full-field

**Fig. 6.9.1 Normal Full-Field Electroretinography (ERG) Responses.** The six basic ERG responses are depicted for a normal individual. After a minimum dark adaptation time of 20 minutes, the dark-adapted or scotopic responses (top four diagrams, A–D) are obtained. (A) The dark-adapted 0.01 ERG (rod response) is obtained using a dim white flash stimulus of 0.01 cd/s/m<sup>2</sup> with a minimum interval of 2 seconds between flashes. (B) The dark-adapted 3.0 ERG (maximal combined rod-cone response) is obtained with a white flash stimulus of 3.0 cd/s/m<sup>2</sup> with a minimum interval of 10 seconds between flashes. (C) The dark-adapted 10.0 ERG is obtained with a white flash stimulus of 10.0 cd/s/m<sup>2</sup> with a minimal interval of 20 seconds between flashes. (D) The dark-adapted 3.0 oscillatory potentials are obtained with a white flash stimulus of 3.0 cd/s/m<sup>2</sup> using high- and low-pass filters. (E–F) After a minimum light adaptation time of 10 minutes, the light-adapted or photopic responses are obtained with a background luminance of 30 cd/s/m<sup>2</sup>. (E) The light-adapted 3.0 ERG (single flash cone response) is obtained with a white flash stimulus of 3.0 cd/s/m<sup>2</sup> with a minimum interval of 0.5 seconds between flashes. (F) The light-adapted 3.0 flicker ERG (30-Hz flicker) is obtained with a white flash stimulus of 3.0 cd/s/m<sup>2</sup> with a flash rate of 30 stimuli per second. (From McCulloch DL, Marmor MF, Brigell MG, Hamilton R, Holder GE, Tzekov R. ISCEV standard for full-field clinical electroretinography [2015 update]. Doc Ophthalmol 2015;130:1–12. Figure 1.)

**Fig. 6.9.2 Illustration of Amplitude and Timing on Full-Field Electroretinogram.** (A) Dark-adapted 0.01 ERG or rod response illustrates latency (dashed black line) and implicit time,  $\tau$  (dashed red line). (B) Dark-adapted 3.0 ERG or maximal combined rod-cone response illustrates both a-wave (solid black line) and b-wave (solid red line) amplitudes.

ERG likewise is useful in evaluating activity in certain uveitic conditions, such as birdshot chorioretinopathy, multiple evanescent white dot syndrome (MEWDS), and acute posterior multiple placoid pigment epitheliopathy (APMPPE).<sup>7</sup> Additionally, full-field ERG testing has a role in ocular trauma in establishing a diagnosis of siderosis when an iron-containing small metallic intraocular foreign body is suspected, and serial ERGs can be helpful in monitoring the health of the retina in these cases.<sup>6</sup>

In a number of retinal conditions, inner retinal dysfunction is a predominant feature. In these cases, many of which lack defining fundus features, ERG can be crucial for accurate diagnosis. Particular inherited conditions, such as congenital stationary night blindness and X-linked retinoschisis, have “electronegative” ERG, in which the waveform to a high-intensity flash under scotopic conditions has a preserved a-wave with a selectively

**Fig. 6.9.3 Full-Field Electroretinogram in Retinitis Pigmentosa.** (A) Dark-adapted 0.01 ERG or rod response to a single flash of bright white light is diminished markedly, consistent with the diagnosis of a retinal degeneration. (B) The light-adapted 3.0 flicker ERG (30 Hz flicker) is completely extinguished.

reduced *b*-wave. Likewise, several acquired conditions, such as central retinal artery occlusion, ischemic central retinal vein occlusion, diffuse unilateral subacute neuroretinitis, and melanoma-associated retinopathy can demonstrate this distinct ERG phenotype along with retinotoxicities from vigabatrin, methanol, and quinine. In these disorders, the selective *b*-wave reduction highlights the predominance of post-photoreceptor inner retinal dysfunction.<sup>6</sup>

Although an ERG phenotype may often be nonspecific, there are a few instances in which electrophysiological responses are pathognomonic for a particular disease. One such disease is cone dystrophy with supernormal rod ERG, a recessively inherited disorder with an underlying genetic defect in *KCNV2*. The electroretinogram is characterized by reduced and delayed photopic responses, reduced and delayed dim flash scotopic responses, and a disproportionate increase in *b*-wave amplitude with relatively small increases in stimulus intensity. The dark-adapted 11.0 ERG has a normal *a*-wave slope with a broadened and squared shape with a late negative *a*-wave peak. In enhanced S-cone syndrome, a recessively inherited disorder associated with a mutation in *NR2E3*, the scotopic 3.0 ERG, although reduced, has a waveform similar to that of the photopic 3.0 ERG, both of which are dominated by S-cone responses. Further, the S-cone ERG is markedly increased compared with normal.<sup>8</sup>

Last, in certain clinical scenarios, a normal ERG can provide reassurance to both the patient and the physician.

## MULTIFOCAL ERG

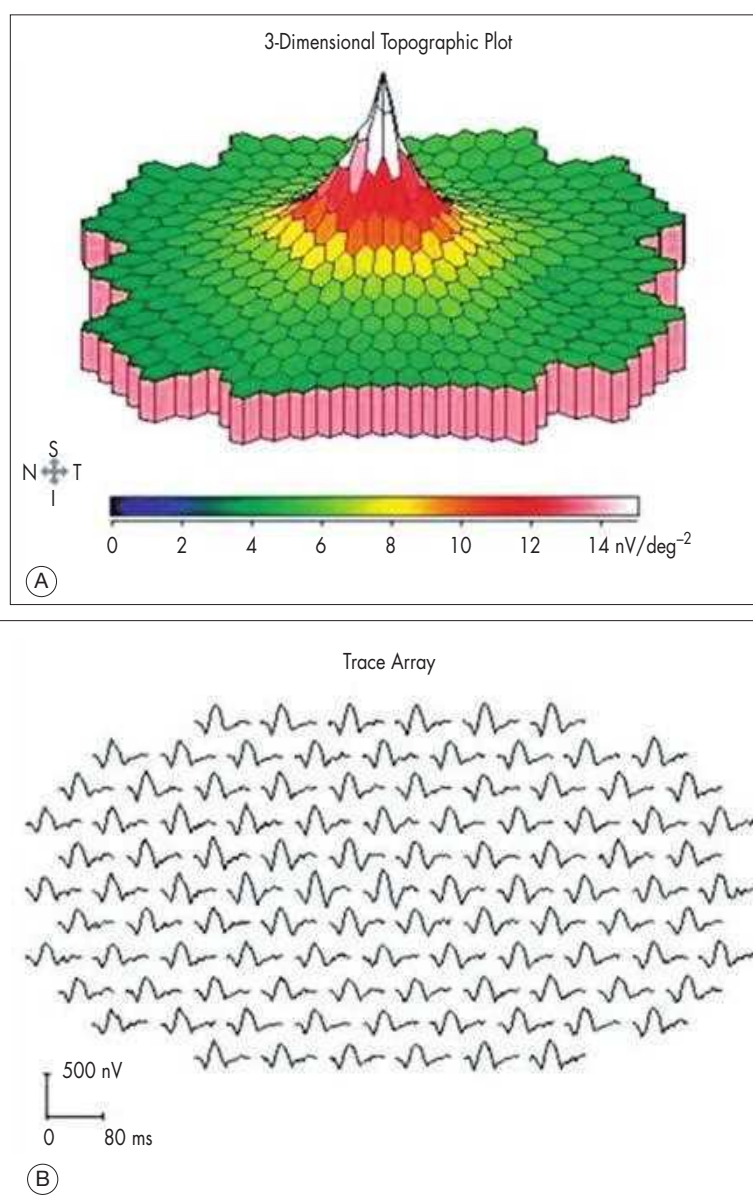

Multifocal ERG (mfERG) has supplanted focal ERG testing and records multiple (61 or 103 hexagons) local ERG responses elicited from the central 40–50° of the retina under light-adapted conditions. These responses are then displayed individually so that abnormal spatial variations can be localized to their corresponding areas in the macula, perimacula, or remaining posterior pole. Worldwide standardized protocols for mfERG testing have been set forth by the ISCEV. mfERG typically displays both an array of individual mfERG traces and a three-dimensional topographic plot<sup>9</sup> (Fig. 6.9.4).

Clinically, mfERG is most useful to assess macular function in patients with unexplained or central loss of vision who may have normal results on full-field ERG. mfERG can aid in the diagnosis of macular diseases, including Stargardt dystrophy, cone dystrophy, and occult macular dystrophy.<sup>9,10</sup>

Multifocal ERG plays an important role in the assessment of drug-induced retinopathy, particularly chloroquine and hydroxychloroquine toxicity. The 2011 American Academy of Ophthalmology revised screening recommendations for chloroquine and hydroxychloroquine toxicity recommended addition of at least one objective test, such as mfERG, spectral-domain optical coherence tomography, or fundus autofluorescence to be used with 10-2 automated visual fields. Further, recommendations specified that mfERG could be used in place of visual fields. Most commonly, mfERG demonstrates a paracentral ring depression of signals around the fovea. This can be followed by central amplitude reduction and widespread depression in advanced retinopathy. In patients taking the medications mentioned above, mfERG can be a quantitative measure of retinal function, potentially providing a more sensitive objective test compared with other modalities, allowing earlier recognition of dysfunction.<sup>11,12</sup>

## ELECTRO-OCULOGRAPHY

EOG measures the difference in electrical potential between the front and the back of the eye, which is mostly a function of the retinal pigment epithelium (RPE) and regulated, in part, by the bestrophin gene. EOG is performed by placing electrodes on the skin of the medial and lateral canthal angles of each eye, in addition to placing a ground electrode on the forehead. The electric potential across the eye is recorded as the patient's eyes move back and forth horizontally under both dark (scotopic) and light (photopic) conditions. Clinical EOG is represented as an Arden ratio (light/dark ratio), which is the ratio of the highest amplitude in light to the lowest amplitude in dark. Normal values should exceed 1.5. Clinically, EOG is most useful in aiding the diagnosis of Best disease and differentiating this entity from adult-onset vitelliform macular dystrophy and pattern dystrophy. Worldwide standardized protocols for EOG testing have been set forth by the ISCEV.<sup>13,14</sup>

# Light and Laser Injury

Caroline R. Bauman

6.10

**Definition:** Structural damage to the retina produced by a light source.

### Key Features

- Mechanism of damage is often photochemical.
- Thermal enhancement of retinal damage is possible.
- Sources include solar eclipse, welding arc, operating microscope, and handheld laser pointer.

### Associated Features

- Delayed appearance of the lesion after the injury by hours to days.
- Variable recovery of vision.
- Severity of damage proportional to duration and intensity of exposure.

## INTRODUCTION

The potentially damaging effects of light on the retina have been recognized since the time of Plato, who described eclipse blindness. Breakdown of the intrinsic ocular protective mechanisms and/or exposure to external high-risk conditions can produce light or photic damage to the retina. The development and severity of light-induced damage depends on a number of factors, including ocular anatomical protective mechanisms, area of tissue involved, and the parameters of the light source, such as the wavelength, duration of exposure, and the total energy exposure.

## LIGHT INTERACTION WITH THE RETINA

The eye primarily perceives radiation in the optical spectrum, comprising the visible (400–760 nm), ultraviolet (UV; 200–400 nm), and infrared (IR; >760 nm) wavelengths. Radiation in this region can be produced by the sun, ophthalmic instruments, and lasers.

Tissue effects produced by light are classified as mechanical, thermal, or photochemical and determined by irradiance (watt per square centimeter [W/cm<sup>2</sup>]), wavelength, duration of light exposure and the absorption of target tissue.<sup>1</sup> Table 6.10.1 outlines tissue effects induced by commercial ophthalmic lasers. Mechanical injury results from high irradiance, short-duration exposure in the nanosecond (10<sup>-9</sup>) to picosecond (10<sup>-12</sup>) range, and the energy strip electrons from molecules and disintegrates target tissue into *plasma*. This is the mechanism of *photodisruption*. At moderate irradiance and exposure greater than 1 microsecond (μsec), thermal effects result from a critical temperature rise in tissue. Elevation of retinal temperature by 10–20°C produces protein denaturation and enzyme inactivation, which results in *photocoagulation*, cellular necrosis, and hemostasis.<sup>2,3</sup> Long visible and infrared (IR) wavelengths produce thermal injury

to the retina and choroid during laser photocoagulation. *Photochemical* or phototoxic effects occur with low-to-moderate irradiances that are below coagulation thresholds and with shorter wavelengths, in particular UV and visible blue wavelengths. Damage to cellular components occurs at temperatures too low to cause thermal destruction, which may account for a delay of 24–48 hours before the appearance of a lesion. Absorption of a photon by the outer electrons of a molecule produces an excited molecular state, which can drive a chemical reaction. Because the energy per photon is inversely proportional to its wavelength, short-wavelength photons have more energy with which to induce a photochemical reaction. Long-wavelength visible light also can induce photochemical changes when tissues are sensitized by an exogenous photosensitizer, as with photodynamic therapy. At intermediate values of irradiance and exposure, more than one of the above mechanisms may be in effect.

The ocular media transmit 75%–90% of electromagnetic radiation in the range of 400–1064 nm.<sup>4</sup> Several mechanisms exist to reduce retinal light exposure. The cornea absorbs most UVB (280–315 nm) and UVC (<280 nm), as well as some IR radiation, and reflects up to 60% of incident light that is not perpendicular to its surface.<sup>4</sup> The lens absorbs most UVA (315–400 nm) and visible blue wavelengths. Intrinsic ocular defenses against retinal light damage include xanthophyll absorption of near-UV and blue light to protect photoreceptors, temperature control by the choroidal circulation, intracellular molecular detoxification of free radicals, and retinal pigment epithelium (RPE)–mediated photoreceptor renewal.<sup>5</sup> Physiological protective mechanisms include squint and blink reflexes, eyebrow ridge, aversion response, and pupillary miosis. Light damage to the retina may occur when protective mechanisms are impaired or as a result of deliberate gazing at a light source. Young patients may be at increased risk because of efficient light transmission through clear ocular media.

## PHOTIC RETINOPATHY

*Photic retinopathy* is a general term for light-induced retinal damage. It is most often caused by inadvertent exposure. The mechanism is typically photochemical, with potential enhancement by elevated tissue temperature and increased blood oxygen tension.<sup>6</sup> Increased chorioretinal pigmentation facilitates light absorption in the RPE and may elevate the background retinal temperature and thermally enhance photochemical damage. It has been hypothesized that retinal defenses against toxic free radicals from light and oxygen are overwhelmed by supranormal light exposure. Damage manifests as a disorder of RPE and photoreceptor outer segments.<sup>7</sup> Retinal phototoxic injury was originally considered permanent; however, visual recovery has been noted in solar retinopathy, laser pointer, welding arc, and operating microscope phototoxicity. Mild photochemical damage may not be symptomatic or visible ophthalmoscopically, and case reports represent the more severe injuries. The extent of retinal injury and the likelihood of visual recovery depend on multiple factors, including the location and area of exposed retina, duration, intensity, spectrum of the light source, and host susceptibility factors, including age, nutritional status, ocular pigmentation, core temperature, clarity of ocular media, and pre-existing retinal disease. Individuals with emmetropia and hyperopia may be at increased risk caused by effective light focusing on the retina.<sup>5</sup> Systemic photosensitizing agents, such as tetracycline and psoralen, may predispose to photochemical damage.

## Solar Retinopathy

Solar retinopathy, which describes retinal injury induced by direct or indirect solar viewing, is also referred to as *foveomacular retinitis*, *photoretinitis*, and *eclipse retinopathy*. The harmful effects of solar viewing have been recognized for centuries. Foveomacular retinitis was initially described

TABLE 6.10.1 Tissue Effects Induced by Commercial Ophthalmic Lasers

Laser Modality	Mechanism of Damage
Argon laser	Photocoagulation
Transpupillary therapy (TTT)	Photocoagulation
Photodynamic therapy (PDT)	Photochemical injury
Neodymium:yttrium–aluminum–garnet (Nd:YAG) laser	Photodisruption

as bilateral decreased vision and foveal lesions in military persons after solar viewing.<sup>8</sup> Solar retinopathy has been associated with religious sun gazing, solar eclipse observing, telescopic solar viewing, sunbathing, psychiatric disorders, and psychotropic drug use.<sup>9</sup> Solar radiation induces photochemical retina damage, which may be enhanced by elevated tissue temperature. Direct solar observation through a 3-mm pupil produces a 4°C temperature rise, which is below thermal damage thresholds.<sup>3</sup> Sustained solar viewing for more than 90 seconds through a constricted pupil exceeds the threshold for photochemical retinal damage.<sup>10</sup> Solar observation through a dilated 7-mm pupil produces a 22°C increase in retinal temperature, which is above photocoagulation thresholds.<sup>3</sup>

Symptoms usually develop 1–4 hours after solar exposure and may include unilateral or bilateral decreased vision, metamorphopsia, scotomata, chromatopsia, photophobia, afterimage, and periorbital ache. Acuity ranges from 20/40–20/200 acutely. A small yellow spot with a gray margin measuring up to 200 µm may develop in the parafoveal area corresponding to the image of the sun (Fig. 6.10.1A).<sup>3,9</sup> A lesion may not be visible in mild cases. Histopathology of acute solar retinopathy demonstrates RPE injury with necrosis, detachment, irregular pigmentation, and minimal photoreceptor damage.<sup>11</sup> Fluorescein angiography (FA) may be normal or reveal RPE transmission defects (see Fig. 6.10.1B). The yellow lesion is replaced by focal depression with RPE mottling or lamellar hole and vision usually improves to 20/20–20/40 within 6 months, although scotomata or metamorphopsia can persist. Optical coherence tomography (OCT; see Fig. 6.10.1C) demonstrates disrupted reflectivity in the outer retina and ellipsoid layer.<sup>12</sup> Ultrastructural findings in experimentally induced solar retinopathy have demonstrated parafoveal cone and

rod outer segment changes and scattered RPE degeneration. The good visual prognosis has been attributed to the resistance of the foveal cones to photochemical damage.<sup>13</sup>

*Eclipse retinopathy* describes similar macular damage after solar eclipse viewing. Evaluation of visual morbidity associated with the full solar eclipse on August 11, 1999, demonstrated abnormal macular appearance in 84% of symptomatic patients with rare cases of persistent symptoms.<sup>14,15</sup> Excessive light exposure in rats has been shown to induce irreversible neuronal apoptosis of retinal cells, which may account for permanent visual impairment as well as gliovascular responses, which may be responsible for the transient clinical symptoms.<sup>16</sup>

No specific therapy exists for solar retinopathy. Further episodes of solar viewing should be discouraged. Eclipse viewing without proper protective eyewear with tested solar filters should be discouraged. Oral corticosteroids have been used to treat acute lesions, but their beneficial effect has not been demonstrated conclusively because vision often improves spontaneously.

## Welding Arc Exposure

Welding arcs emit radiation, and the most common injury is keratitis caused by corneal absorption of UV rays. Retinal injury is rare but can occur after a welding arc viewing without proper ocular protection.<sup>17</sup> The retinal temperature increase is below photocoagulation thresholds, and injury is produced by photochemical effects from UV and short blue wavelength exposure. The symptoms and clinical course are similar to solar retinopathy. A yellow edematous foveal lesion develops acutely (Fig. 6.10.2),

**Fig. 6.10.1 Solar Retinopathy.** In the right eye (A) and left eye (B), of the same patient. (C) Fluorescein angiography of solar retinopathy in the left eye. Transmission hyperfluorescence corresponds to the retinal pigment epithelium defect. (D) Optical coherence tomography of solar retinopathy, left eye.

**Fig. 6.10.3 Acute Retinal Phototoxicity, 2 Weeks After Cataract Surgery.** (A) Perifoveal fluorescein mottling in the early-stage angiogram. (B) Modest fluorescein leakage and retinal pigment mottling in the late phase. Visual acuity is 20/60. (Courtesy Gordon A. Byrnes, MD.)

which is replaced over time by RPE irregularity or lamellar hole. No effective therapy exists, and vision usually improves with time, with permanent vision effects being rare.

Phototoxicity has also been described following brief incidental light exposure from camera flashes or welding arcs in four patients who were taking photosensitizing drugs (hydrochlorothiazide, furosemide, allopurinol, and benzodiazepines).<sup>18</sup>

### Lightning Maculopathy

Lightning maculopathy describes acute visual loss and macular changes after lightning injury. Vision loss may be severe to light perception and lesions may include macular edema, macular hole, cyst, or a solar retinopathy-like picture, cataract, retinal detachment, retinal artery occlusion, and relative afferent pupillary defect.<sup>19</sup> Visual recovery often occurs over time, even with severe maculopathy. High-dose intravenous methylprednisolone treatment may play a role in vision recovery, and its use was associated with reversal of lightning-induced blindness in two cases.<sup>20</sup>

### Retinal Phototoxicity From Ophthalmic Instruments

Ophthalmologists use a variety of powerful light sources. Retinal injury caused by light exposure from the operating microscope and endoillumination has been described. Iatrogenic phototoxicity has been reported after cataract extraction, combined anterior segment procedures, and

vitreous surgery.<sup>7</sup> The most frequent cause is the operating microscope as initially described after uncomplicated extracapsular cataract extraction, with reported incidence ranging from 0% to 7%.<sup>21–23</sup> The mechanism of intraoperative phototoxicity is photochemical, with potential thermal enhancement. Because operating microscopes generate little UV radiation, photochemical damage probably is caused by short-wavelength visible blue and green light. The incorporation of UV and IR filters in the intraocular lens (IOL) and microscope may reduce, but do not completely eliminate, the risk of photic and thermal effects, respectively, as demonstrated by experimentally induced human photic retinal injury in a blind phakic eye after 60 minutes of operating microscope exposure with UV and IR filtered light.<sup>24</sup>

Few patients show symptoms immediately after exposure, and the level of vision depends on lesion size and location. A foveal lesion can produce severe permanent vision loss, whereas an eccentric lesion is compatible with good acuity and pericentral scotoma. The lesion shape matches the surgical illuminating source. Immediately after exposure, there is little evidence of macular pathology but within 24–48 hours, a yellow lesion, measuring 0.5–2.0 disc diameter at the level of the RPE, with retinal edema develops. FA acutely reveals dye leakage (Fig. 6.10.3), which may simulate choroidal neovascularization (CNV). Over weeks, the yellow lesion is replaced by RPE clumping and atrophy (Fig. 6.10.4A), which correspond angiographically to blocking and transmission defects, respectively (see Fig. 6.10.4B). Other long-term sequelae include postoperative erythropsia, retinal surface wrinkling, and choroidal neovascularization.<sup>25,26</sup> Mild light-induced retinal injuries may be overlooked clinically because subtle postoperative pigmentary changes may be attributable to other causes.

**Fig. 6.10.4 Chronic Retinal Phototoxicity in the Left Eye.** (A) Visual acuity is 20/50 (6/15). A well-defined area of retinal pigment epithelium mottling is present. The patient also has congenital retinal venous tortuosity. (B) Fluorescein angiography reveals blocking and transmission defects without late fluorescein leakage. (Courtesy Gordon A. Byrnes, MD.)

Histopathology of acute operating microscope-induced injury has revealed RPE and photoreceptor damage.<sup>27</sup> In primates, early photic lesions have demonstrated photoreceptor damage and disruption of RPE tight junctions, with regeneration of photoreceptor outer segments 3–5 months after injury.<sup>26</sup> This may correspond to recovery of vision after injury noted in some human eyes. Operating microscope phototoxicity has been associated with surgical factors, including microscope brightness, wavelength of light exposure, surgical duration, and technique. Retinal phototoxic lesions may occur after short-duration (under 30 minutes) phacoemulsification and were associated with near emmetropia and diabetic retinopathy.<sup>28</sup> The risk of photic damage may increase after IOL insertion, which can focus incoming light on the retina. Patient susceptibility factors include increased body temperature and blood oxygenation, chorioretinal pigmentation, pre-existing maculopathy, pupillary dilatation, diabetes mellitus, retinal vascular disease, deficiencies of either ascorbic acid or vitamin A, and photosensitizer use. Photic damage secondary to endoillumination during vitrectomy is uncommon and can be avoided by minimizing length of surgery and light output, filters, maximizing light pipe distance from the retina and using eccentric endoillumination techniques.<sup>29</sup>

There is no specific treatment for acute lesions, and spontaneous visual improvement usually occurs within months, even when lesions involve the macula. Methods to reduce the risk include reduction of coaxial illumination and operative time, use of IR and UV filters in the microscope and IOL, placement of an air bubble in the anterior chamber to defocus incident light, and use of a corneal cover.

The irradiance produced by the indirect ophthalmoscope and the fundus camera is lower than experimentally determined retinal injury thresholds. Furthermore, the total energy delivered to the eye is less under nonoperative conditions than in operative conditions. These instruments have not been shown to produce acute retinal injury in humans; however, prolonged exposure to the indirect ophthalmoscope has been shown to produce lesions in primates. The cumulative effect of repeated examination is unknown, and it is recommended that retinal examinations be performed with the minimal illumination required.

## LIGHT EXPOSURE AND AGE-RELATED MACULAR DEGENERATION

An association between long-term solar exposure and age-related macular degeneration (AMD) was considered when AMD was found to be less common in patients with nuclear cataract.<sup>30</sup> Histopathology of acute photic injury reveals damage to the macular RPE and photoreceptors, which is the same tissue depth and geographical location as changes observed in AMD.<sup>23</sup> Solar viewing acutely damages the RPE and produces RPE pigmentary irregularities, which are similar in appearance to those in AMD, although the diffuse thickening of Bruch's membrane noted in AMD does

not occur with damage caused by solar viewing.<sup>11</sup> The relationship between light and AMD has been evaluated with epidemiological studies. In the Chesapeake Bay watermen study, no association was found between cumulative UVA or UVB exposure and mild or advanced AMD.<sup>31</sup> An association was noted between blue or visible light exposure during the preceding 20 years and the risk of developing advanced AMD.<sup>32</sup> In the Beaver Dam Eye Study, no association was found between estimated ambient UVB exposure and AMD.<sup>33</sup> The amount of outdoor leisure time in summer was associated with increased retinal pigmentation in men and late AMD in both men and women. To date, no study has yet conclusively defined the relationship between long-term UV light exposure and AMD. Until this is clarified, sunglasses to filter UV and blue light may be considered for individuals at risk, such as those with pseudo-phakia and those with aphakia who do not wear UV-protective intraocular lenses and individuals with decreased ocular pigmentation or at risk of AMD.<sup>5</sup>

## LASER INJURY

Laser applications in industrial, military, and laboratory situations account for many cases of accidental retinal injury, resulting from either direct laser exposure or its reflections. It usually occurs when the laser is fired inadvertently around an individual without ocular protection. The retinal tissue damage depends on the laser parameters and ranges from a small, subtle lesion to macular hole formation and extensive hemorrhage and disruption of the retina and choroid. Accidental foveal photocoagulation can produce immediate loss of vision up to 20/200, with a foveal cyst or yellow discoloration of the RPE (Fig. 6.10.5). Long-term evaluation may reveal RPE irregularities, epiretinal membrane, macular hole, and gliosis. Recovery of vision is variable and is related to the extent and location of the initial injury.<sup>34</sup> On the basis of findings from animal models, corticosteroids have been variably used to treat laser-induced retinal injuries.

Laser operators and persons in the laser vicinity are at risk from laser light scattered from optical interfaces, such as contact lenses and mirrors; therefore protective goggles should be worn by these individuals. Lasers for retinal photocoagulation contain filters to protect the operator. Decreased color discrimination in a tritan color-confusion axis had been noted in ophthalmologists who used argon blue-green laser.<sup>35</sup> This may have been caused by chronic exposure to reflections from the argon blue aiming beam, so currently lasers use either red or green aiming beam to minimize operator risk.

## LASER POINTERS

Laser pointers are portable low-energy devices that emit a narrow, coherent, low-powered laser beam. In the United States, lasers are classified by American National Standards Institute and the U.S. Food and Drug Administration (FDA) specifications that a handheld laser for use as

**Fig. 6.10.5 Laser Pointer-Induced Macular Injury in a 6-Year-Old Boy.** Vision measured 20/200 acutely in both eyes (OU), and color photograph revealed yellow streaks radiating from the fovea center (A–B). Optical coherence tomography (OCT) revealed blurring of the ellipsoid and interdigitation zones and opacification of Henle's layer (C–D). Three years after the injury, vision improved to 20/40 with residual focal outer retinal defect (E–F).

a pointer must be a class 1, 2 (<1 milliwatt [mW]), 2A, or 3A (1–5 mW) device. In contrast, class 3B lasers generate 5–500 mW, and class 4 lasers generate over 500 mW.

Laser pointers are common and have the potential for misuse that could lead to inadvertent ocular exposure and secondary retinal damage.<sup>36–40</sup> It is difficult to produce ocular injury with a low-energy class 3A laser pointer unless with inappropriate, prolonged, foveal exposure. Certain individual factors, such as age, pre-existing maculopathy, and clarity of the ocular media, play a role in determining susceptibility. The mechanism depends on the wavelength but appears to be thermal chorioretinal damage or phototoxicity. Handheld lasers are readily available on the Internet from dubious sources that may not comply with FDA standards, with power outputs exceeding class 3A, or may have inaccurate device labeling. Handheld devices that exceed recommended standards can produce permanent retinal injury and visual impairment with resultant photoreceptor damage as shown by optical coherence tomography (OCT).<sup>40–42</sup>

Damage manifests as unilateral or bilateral transient visual abnormalities, scotoma, and perimacular RPE disturbances.<sup>36</sup> OCT reveals acute photoreceptor damage and opacification of Henle's layer, with some recovery of vision over time (see Fig. 6.10.5).<sup>41,42</sup> Systemic corticosteroids have been shown to improve lesions in primate models of laser injury.

## COMPLICATIONS OF THERAPEUTIC RETINAL LASER PHOTOCOAGULATION

With proper laser use, complications are rare, but risks and informed consent should be discussed with patients when laser is used clinically. Inadvertent photocoagulation of the fovea, cornea, iris, or lens can be minimized with careful technique and appropriate laser settings. The risk

of choroidal effusion after extensive panretinal photocoagulation can be reduced by spreading treatment over multiple sessions. Secondary CNV and hemorrhage caused by damage to Bruch's membrane can be minimized by reducing laser intensity and duration and by avoiding small spot sizes (50  $\mu$ m).

[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Closure of retinal breaks by scleral indentation.

## Key Features

- Identification, localization, and treatment of retinal breaks.
- Scleral imbrication.

## Associated Features

- Anatomical success rate high—generally 80%–90%.
- External drainage of subretinal fluid sometimes performed.
- Can be combined with vitrectomy surgery.

## INTRODUCTION

Although primary vitrectomy is being increasingly utilized, an essential surgical procedure for the repair of certain rhegmatogenous retinal detachments is scleral buckling. The goal of scleral buckling is to close retinal breaks by indenting the eye wall, thus preventing the passage of liquefied vitreous into the subretinal space. This flexible approach incorporates the benefits and advantages of different techniques and materials, maximizing the rate of anatomical and visual success while minimizing potential complications.

## HISTORICAL REVIEW

Recognition of vitreoretinal traction and retinal breaks in the pathogenesis of retinal detachment by Gonin in 1919 ushered in the era of repair, in which drainage of subretinal fluid and treatment of retinal breaks were employed. Custodis, 30 years later, introduced the concept of scleral buckling. The introduction of the binocular indirect ophthalmoscope and scleral depression by Schepens in 1951 revolutionized the localization of peripheral retinal pathology. Advancements were made when Schepens combined scleral dissection, diathermy, and intrascleral implantation of silicone buckles for scleral buckling. Lincoff et al. refined Custodis' procedure by using silicone sponge explants and cryotherapy.<sup>1,2</sup>

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

The diagnosis of rhegmatogenous retinal detachment is suggested by symptoms of floaters, photopsia, peripheral vision loss, and decreased central vision in cases of macular involvement. In patients with clear media, the diagnosis is confirmed by indirect ophthalmoscopy with scleral depression. Slit-lamp biomicroscopy with a three-mirror contact lens may also be helpful in identification of retinal pathology and localization of retinal breaks. The location and type of retinal breaks, as well as the size and duration of retinal detachment, are factors that help determine the timing and type of scleral buckling procedure performed.

Optical coherence tomography (OCT) is useful in documenting subretinal fluid, especially in the macula, and the extent of any accompanying

intraretinal edema or epiretinal proliferation. In patients with opaque media, the retinal status may not be visualized. Diagnostic ultrasonography is critical in establishing retinal detachment.

## DIFFERENTIAL DIAGNOSIS

Not all retinal detachments are rhegmatogenous. Other causes include tractional retinal detachments (as in advanced diabetic retinopathy), exudative retinal detachments (as in uveitic conditions, tumors, or uveal effusion syndrome), and combined detachments.

## ALTERNATIVES TO SCLERAL BUCKLING

Rhegmatogenous retinal detachments can be repaired by other surgical techniques. Pneumatic retinopexy involves injection of an expansible gas bubble into the vitreous and postoperative positioning so that the gas bubble closes the retinal break.<sup>3</sup> The break is treated with either cryopexy or laser photocoagulation. Pneumatic retinopexy is generally reserved for detachments in the superior hemiretina with a single break or several closely spaced breaks with clinical posterior vitreous detachment and no inferior retinal pathology.

Vitrectomy techniques, described in Chapter 6.12, also can be used to repair rhegmatogenous retinal detachments. The indications for scleral buckling versus pneumatic retinopexy or vitrectomy remain controversial.

## ANESTHESIA

Scleral buckling can be performed with the patient placed under local or general anesthesia. The anesthetic technique that is used is a matter of surgeon and patient preference. The advantages of local anesthesia include shorter operating time, quicker postoperative recovery, and possibly decreased morbidity and mortality. However, retrobulbar placement of local anesthetic is not without risk. Perforation of the globe, particularly in patients with myopia, and damage to the optic nerve may result in permanent visual loss. Respiratory arrest and grand mal seizures also have been reported with inadvertent intrathecal administration of retrobulbar anesthetic. These complications can be minimized with a subconjunctival or a peribulbar technique.<sup>4,5</sup>

## GENERAL TECHNIQUES

A peritomy (conjunctival opening) is performed either at the limbus or several millimeters posterior to it. Because of considerable conjunctival manipulation, radial relaxation incisions are recommended to prevent tearing. In patients who have filtering blebs or recent limbal wounds, the peritomy can be extended posteriorly to avoid those areas. If only one or two quadrants are to be buckled, conjunctiva and Tenon's capsule can be reflected in the required quadrants only (Video 6.11.1).

After the peritomy, the space between Tenon's capsule and sclera is entered, the muscle insertion is engaged with a muscle hook, and the connections to Tenon's capsule are identified and separated from the muscle. A traction suture is placed around each of the four rectus muscles. After all recti have been isolated, the surface of the sclera is inspected for evidence of thinning (most common superotemporally), staphyloma, and anomalous vortex veins. Traction on the extraocular muscle insertions may

See clip:  
6.11.1

**Fig. 6.11.1** Felt-tip pen purple mark on sclera denoting posterior margin of small flap tear.

produce a bardycardic oculocardiac reflex, so it is important to carefully monitor patient's heart rate during this step.

No aspect of scleral buckling is more critical than accurate placement of the buckle, requiring precise localization of retinal breaks on the scleral surface. For small flap tears or holes, a single mark on the posterior edge of the break is sufficient. Larger flap tears and nonradial tears require localization of both the anterior and posterior extents of the break (Fig. 6.11.1) (Video 6.11.2).

See clip:  
6.11.2

## Treatment of Retinal Breaks

The rationale for the treatment of retinal breaks is to create an adhesion between the retinal pigment epithelium (RPE) and the retina. This is accomplished by inducing a thermal injury by using one of three energy sources: diathermy, cryotherapy, or laser. The morphological and cellular response of the retina and RPE to each of these energy sources is essentially similar. After 2 weeks, all three modalities show comparable effects on the retinal adhesive force.<sup>6</sup>

## Explant Scleral Buckling Techniques

Explant techniques allow the placement of buckling elements to support retinal pathology.<sup>7</sup> Explants are made of either solid silicone rubber or silicone sponges and come in a variety of sizes and shapes. They are secured to the sclera with partial-thickness scleral sutures (Video 6.11.2). For most detachments, the selected element is not as important as the accurate localization and placement of it. Proper placement requires an effective suturing technique, involving the use of a spatula needle with a 5-0 nonabsorbable suture, such as polyester, nylon, or polypropylene. The suture is placed either snug with the band (buckle height achieved by circumferential tightening of the band) or 1 mm or more on each side (buckle height achieved by suture imbrication. To ensure that the most posterior edge of the break is supported, the posterior suture is placed a minimum of 2–3 mm posterior to the scleral localization mark.

Element placement can be either segmental or encircling. Segmental buckles usually are reserved for detachments with single or closely spaced retinal breaks, <1 clock hour in extent. Although segmental buckles close isolated tears effectively, they are less useful in preventing new breaks because they provide no support elsewhere. Encircling procedures are particularly indicated in patients with the following conditions:

- Multiple breaks in different quadrants.
- Aphakia.
- Pseudo-phakia.
- Myopia.
- Diffuse vitreoretinal pathology, such as extensive lattice degeneration or vitreoretinal degeneration.
- Proliferative vitreoretinopathy (PVR).

**Fig. 6.11.2** Location of preferred drainage sites.

The anteroposterior position of the encircling element depends on the location of the pathology to be supported. When retinal breaks in the detached retina are associated with traction, the buckle should be positioned such that the posterior edge of the break lies on the posterior crest of the buckle. The buckling effect should extend for 30° on either side of the tear and extend anteriorly to the ora serrata. When the encircling element supports pathology in the attached retina, such as a retinal break, it should be positioned to support the most posterior aspect of the pathology. If no specific pathology is to be supported, the encircling element should support the posterior margin of the vitreous base.

The height of the encircling element (imbrication) can be obtained in two ways. For thin encircling elements, such as solid silicone bands, the explant can be shortened in relation to the circumference of the globe. The second method is via suture placement. This technique is used with wider and thicker explants and does not require the element to be shortened in relation to the ocular circumference. The farther apart the bites of the mattress suture are placed, the greater the height when the sutures are tightened<sup>7</sup> (Video 6.11.1).

See clip:  
6.11.1

## Drainage of Subretinal Fluid

Indications for drainage of subretinal fluid during scleral buckling remain controversial. Some authors believe that most cases can be managed without drainage, whereas others believe that drainage is a crucial aspect of the procedure.<sup>7,8</sup> The rationale for drainage is twofold:

- To diminish intraocular volume, allowing elevation of the buckle without elevating intraocular pressure (IOP).
- To allow the retina to settle on the elevated buckle by removing fluid from the subretinal space.

Effective drainage places the retinal breaks in juxtaposition to the choroid overlying the buckle, thus facilitating closure.

The selection of an external drainage site is affected by several factors (Fig. 6.11.2). Although the location of subretinal fluid is a primary concern, it is not necessary to drain where the amount of fluid is greatest but, rather, where there is adequate fluid to safely enter the subretinal space. Whenever possible, it is preferable to drain just above or below the horizontal meridian, either temporally or nasally (see Fig. 6.11.2), avoiding the major choroidal vessels and vortex veins.

Drainage in the posterior third of the bed of the buckle is preferred. This provides adequate support of the drainage site in the event of a complication, such as retinal incarceration or choroidal hemorrhage, and immediate closure when the buckle is tightened. If, because of the configuration

See clip:  
6.11.3

of the detachment or the position of the buckle, it is not possible to drain in the bed of the buckle, closure of the site with a suture should be considered. Drainage outside the bed of the buckle allows the buckle to be pulled up as drainage proceeds. Entry through the choroid and into the subretinal space is performed with a needle (27–30 gauge), with the presence of fluid signifying entry into the subretinal space. As the fluid drains, it is important to maintain a relatively normal and constant IOP to prevent retinal incarceration and choroidal hemorrhage (Video 6.11.3).

After successful drainage and closure of the site, the buckle is positioned with the appropriate preplaced scleral sutures. Any suture that overlies a retinal break is tightened first. The encircling band, if present, is then adjusted with a silicone sleeve. As the sutures are tightened, they are secured with temporary ties, as this allows easy adjustment of buckle height and position, and the optic nerve is inspected for perfusion. Once the buckle is positioned and the band adjusted, the fundus is inspected again to determine the status of the breaks and perfusion of the optic nerve.

Nondrainage procedures can be used to reattach the retina, with success rates comparable with those of drainage procedures. The primary advantage of a nondrainage procedure is that it avoids the potential complications associated with drainage. In eyes with relatively shallow detachments, the eye may soften enough after scleral depression and cryopexy to allow placement of the buckle without IOP problems. Waiting several minutes between tightening of the scleral sutures also may soften the eye. However, nondrainage techniques often require the IOP to be lowered by additional medical or surgical means. An injection of a small volume of air or gas (0.2–0.4 cc of 100% SF<sub>6</sub> or C<sub>3</sub>F<sub>8</sub>) is often used as an adjunct in drainage or nondrainage buckles, to promote closure of the retinal break.

## Chandelier-Assisted Scleral Buckling

Chandelier-assisted scleral buckling is a relatively novel technique in which traditional scleral buckle placement and maneuvers (e.g., marking of retinal breaks, cryopexy, and external drainage) are performed under wide-angle visualization through the operating microscope. The visualization is enabled by endoillumination provided by a small-gauge fiberoptic chandelier placed near the beginning of the case. The advantage of this procedure is that it allows for identification of all retinal breaks even in the far periphery, which is very helpful to less experienced surgeons. It is also a great tool for teaching as it allows simultaneous viewing by the surgeon and vitreoretinal fellow. The chief disadvantage of the chandelier during primary scleral buckle is that it requires entry into the vitreous cavity and carries a small risk of vitreous incarceration at the sclerotomy site.

## Closure

After final adjustments, the sutures are tied and the knots rotated posteriorly. Tenon's capsule and the globe can then be irrigated with an antibiotic solution. Retrobulbar irrigation with 0.75% bupivacaine significantly decreases postoperative pain after general or local anesthesia.

Tenon's capsule is then identified in all quadrants. A layered closure, initially closing Tenon's capsule to the muscle insertions, ensures that the explant and the nonabsorbable sutures are covered by Tenon's capsule and removes the tension on the conjunctival closure, minimizing the possibility of buckle erosion. During conjunctival closure, the relaxation incisions are typically closed with 6-0 plain gut suture or 7-0 vicryl. The conjunctiva is secured at the limbus with one or more sutures.

Long-term, a fibrous capsule forms overlying the scleral buckle, which maintains the scleral buckle position and indentation effect (Figs. 6.11.3 and 6.11.4).

## COMPLICATIONS

### Intraoperative Complications

#### Scleral Perforation

Scleral perforation during suture placement is a potentially devastating complication. Perforation usually is noticed at the time of suture placement and is heralded by the presentation of blood, pigment, or subretinal fluid through the suture tract.

#### Drainage Complications

The most common drainage complications are retinal incarceration and choroidal or subretinal hemorrhage.<sup>8</sup> Retinal incarceration may occur

**Figure 6.11.3** Cross-sectional hematoxylin and eosin–stained section of an eye with history of scleral buckling procedure. Fibrous capsule outlining the prior location of buckling element is observed (black arrows).

**Figure 6.11.4** Intraoperative image of an eye undergoing scleral buckle removal demonstrates the fibrous capsule being cut and reflected by the blade longitudinally along the axis of the buckling element (yellow arrow).

despite attempts to avoid large fluctuations in IOP during drainage, and is identified by the characteristic dimpled appearance of the retina over the site. Minimal degrees of incarceration rarely result in retinal breaks, but large amounts of incarceration require support with a buckle.

Choroidal or subretinal hemorrhage is perhaps the most feared complication of subretinal fluid drainage. This usually occurs at the time of choroidal perforation and is marked by the appearance of blood at the site. If this occurs, the drainage site should be closed as quickly as possible with either the buckle or a suture and the IOP elevated above the systolic perfusion pressure. If the drainage site is temporal, the eye should be positioned to place the located site as inferiorly as possible to prevent gravitation of the blood to the fovea.

### Postoperative Complications

#### Glaucoma

A variety of secondary glaucomas may develop after scleral buckling. Angle closure after scleral buckling may take place with or without pupillary block. One presumed mechanism of closure is shallow detachment of the ciliary body, which results in anterior displacement of the ciliary body and occlusion of the angle. Anterior segment ischemia also may cause glaucoma.

### Infection and Extrusion

Scleral buckling materials constitute foreign bodies and therefore carry the risk of infection and extrusion. The incidence of explant infection and extrusion is about 1%. Effective management of infected scleral buckling material usually requires removal. Topical and systemic antibiotics occasionally result in symptomatic improvement, but they are rarely curative. Removal of the scleral buckling material carries a redetachment risk of 4%–33%.

### Choroidal Effusion

Accumulation of serous or serosanguinous fluid in the suprachoroidal space is relatively common after scleral buckling, referred to as a choroidal (or ciliary body) effusion. Choroidal effusion is related to the size and extent of the scleral buckle.<sup>9</sup>

### Cystoid Macular Edema and Residual Subretinal Fluid

Using cryotherapy and explant techniques, the incidence of angiographic cystoid macular edema (CME) 4–6 weeks after surgery in phakic eyes is 25%–28%, and typically resolves spontaneously.<sup>10</sup> Additional therapies, such as corticosteroids, may be needed for resolution.<sup>11</sup>

### Macular Pucker

Macular pucker is a major cause of decreased vision after scleral buckling, with the incidence in the range of 3%–17%.<sup>12</sup> Risk factors identified include preoperative PVR of grade B or greater, age, total retinal detachment, and vitreous loss during drainage.<sup>10</sup>

### Diplopia

The incidence of postoperative diplopia is low. In a series of 750 patients who underwent scleral buckling for retinal reattachment, 3.3% complained of diplopia postoperatively.<sup>13</sup> The incidence of diplopia is greater after reoperations involving buckle revision and with larger buckles.

### Changes in Refractive Error

The extent of change in refractive error after scleral buckling depends on the surgical technique employed. Segmental buckles have little effect on refractive error. However, large radial elements, such as full-thickness sponges that extend anteriorly beyond the ora serrata, may induce an irregular astigmatism. Encircling procedures induce the greatest change in refractive error, greater for phakic than for aphakic eyes, because of the anterior displacement of the lens, resulting in an increased myopic shift.<sup>14</sup>

## OUTCOME

The anatomical results following scleral buckling are impressive, with an overall reattachment rate of around 90%. Unfortunately, the visual results after scleral buckling do not parallel the anatomical results. Multiple factors correlate with visual and anatomical prognosis. Detachments with the macula attached (macula-on detachments) at the time of surgery have a significantly better prognosis compared with detachments in which the macula is involved. Some series demonstrate successful anatomical reattachment in 99% of cases of macula-on retinal detachments.<sup>15,16</sup> However, decreased visual acuity can occur, usually caused by postoperative macular changes, such as CME or macular pucker. Approximately 10% of patients who have macula-on detachments suffer a visual loss of two Snellen lines or greater with respect to their preoperative vision.

Detachment of the macula results in a variable degree of permanent photoreceptor damage that correlates with the duration of the detachment.<sup>17</sup> Macula-off detachments are usually larger and of greater duration compared with macula-on detachments; therefore, it is not surprising that macula-off retinal detachments have a lower rate of success. Although the overall anatomical success rate for macula-off detachments is at least 90%,

**Fig. 6.11.5** (A) Optical coherence tomography of acute retinal detachment of 3 days' duration. Note the retinal edema. (B) Optical coherence tomography of same eye 6 weeks after scleral buckling. Note the persistent subfoveal fluid despite resolution of retinal edema and retinal attachment.

only 40%–60% of patients have a final visual acuity of 20/50 or better.<sup>18–20</sup> Preoperatively, OCT documents the status of the macula and the presence of retinal edema (Fig. 6.11.5). Postoperatively, OCT may demonstrate the presence of CME or residual subretinal fluid.<sup>21</sup>

# Vitrectomy

Michael Engelbert, Stanley Chang

# 6.12

**IN THIS CHAPTER**  
Additional content  
available online at  
[ExpertConsult.com](http://ExpertConsult.com)

**Definition:** Vitrectomy is an intraocular surgery during which the vitreous is removed to allow for adjunctive procedures to repair retinal and/or macular pathology or to remove foreign, abnormal, or dislocated tissue or material from the posterior segment or to place therapeutic medications, devices, or tamponades into the eye.

## Key Features

Three ports in pars plana to accommodate:

- Infusion to replace intraocular volume and maintain IOP and to infuse vitreous tamponade.
- Endoillumination cutter, forceps, scissors, endodiatheirmy, endolaser.
- Visualization with contact or noncontact viewing system.

## INTRODUCTION

Since its genesis, remarkable advances in vitreous surgery have established this microsurgical procedure as the second-most common intraocular operation after cataract extraction. Progress in two major areas has fueled the extraordinarily rapid growth in vitreous surgical techniques:

- Understanding of the pathoanatomical changes that affect the retina and vitreous.
- Introduction of new technology and instrumentation.

In the early years, vitrectomy was used to restore ambulatory vision in eyes that were otherwise destined to become blind. Both removal of opacified vitreous and removal of fibrovascular tissue in diabetic retinopathy often resulted in restoration of functional vision. Eyes that had complicated retinal detachments, such as those associated with proliferative vitreoretinopathy or that resulted from severe penetrating injury, were regarded as inoperable previously. As advances in technology continued and the safety of the vitrectomy procedure was established, the focus shifted to newer applications (e.g., macular surgery). The goals of this surgery are to improve and restore central visual acuity in such conditions as macular pucker, macular hole, and retinal detachment.

## HISTORICAL REVIEW

In 1970, Machemer and Parel introduced the first instrument to cut and remove vitreous, and the first vitrectomy procedure was in a patient with diabetes who had a long-standing vitreous hemorrhage (Video 6.12.1).

See clip:  
6.12.1

## PREOPERATIVE EVALUATION AND DIAGNOSTIC APPROACH

The preoperative evaluation of patients who are to undergo vitrectomy includes a careful examination of the eye and assessment of the patient's medical status and risk of anesthesia-related complications. The surgeon reviews the planned procedure with the patient to explain expected outcomes and potential benefits and risks.

Slit-lamp examination is used to evaluate the anterior segment structures, whereas indirect biomicroscopy allows for assessment of vitreoretinal anatomy. When a gas bubble tamponade is planned, the depth of the anterior chamber is assessed because a large bubble may result in shallowing and angle-closure glaucoma. The cornea, size of the dilated pupil, and clarity of the lens are noted to ensure that, intraoperatively, the retina can be visualized adequately. In pseudo-phakic eyes, the type of intraocular lens (IOL) and its composition are studied. Because of its hydrophobic properties, a silicone IOL may develop condensation on its surface during fluid–air exchange, and the placement of silicone oil intravitreally may result in adhesion of oil droplets to the implant surface, which reduces the clarity of the optical zone. Gonioscopic evaluation is carried out in patients with diabetes and those who have inflammatory conditions.

The status of the vitreous is best studied using indirect biomicroscopy—either a noncontact +78.00 diopters (D) or +90.00 D lens or a contact lens may be used. The absence or presence of separation of the posterior hyaloid surface is determined first, as this finding is critical to the surgical approach in macular conditions. These findings are supplemented by those of careful indirect ophthalmoscopy, which provides information about the severity of epiretinal membrane (ERM) proliferation, the location of retinal breaks, and anatomical changes in the vitreous base and peripheral retinal structures. Optical coherence tomography (OCT) as an adjunctive diagnostic tool has revolutionized the assessment of the vitreous–retinal interface as well as the retina, retinal pigment epithelium (RPE), and subretinal space at a close to ultrastructural level in a noninvasive fashion. This has greatly facilitated the distinction between “true” macular holes, pseudo- and lamellar holes, as well as cystic macular edema. Sensitivity, specificity, and reproducibility exceed that of a contact lens examination. It is also increasingly being used to help prognosticate surgical outcomes for macular hole and macula-off detachment surgery.

In cases of media opacity, ultrasonographic evaluation provides an accurate map of the vitreoretinal relationships. In particular, the mobility of retinal detachment, delineation of tractional regions, and localization of vitreous or subretinal hemorrhage may be depicted. The location and dimensions of prior scleral buckling elements may be determined. In trauma situations, ancillary tests using computed tomography or orbital radiographic analysis may be necessary to aid in the localization of foreign bodies and damage to periocular structures.

## INDICATIONS AND ALTERNATIVES TO SURGERY

The surgical indications for vitrectomy are given in [Box 6.12.1](#). These include a wide range of conditions, some of which involve the vitreous or retina focally, whereas others represent more diffuse processes. Other chapters in this book describe the alternative medical approaches for many of the listed conditions.

## ANESTHESIA

The majority of vitrectomies are carried out under local anesthesia (retrobulbar block, peribulbar block, or subconjunctival irrigation) with monitored anesthesia care. In instances of extreme patient apprehension or an inability to cooperate, general anesthesia is required. When using general anesthesia and intraoperative gas administration, it is important to discontinue inhalation of nitrous oxide at least 20 minutes prior to the final

### BOX 6.12.1 Indications for Vitrectomy

#### Diabetic Retinopathy

- Nonclearing or repeated vitreous hemorrhage
- Traction retinal detachment
- Combined traction and rhegmatogenous retinal detachment
- Progressive fibrovascular proliferation
- Macular distortion by fibrovascular proliferation
- Macular edema that results from a taut posterior hyaloid

#### Retinal Detachment

- Retinal detachment with proliferative vitreoretinopathy
- Giant retinal tears
- Retinal detachment with posterior retinal breaks
- Some primary retinal detachments

#### Complications of Anterior Segment Surgery

- Dislocated lens fragments
- Dislocated intraocular lens
- Aphakic or pseudo-phakic cystoid macular edema
- Endophthalmitis
- Choroidal hemorrhage
- Epithelial downgrowth
- Anesthetic needle perforation

#### Trauma

- Hyphema evacuation
- Traumatic cataract or dislocated lens
- Posterior penetration injuries with vitreous hemorrhage and/or retinal detachment
- Reactive intraocular foreign body
- Subretinal membranes or hemorrhage
- Traumatic macular holes

#### Macular Surgery

- Macular pucker
- Macular hole
- Massive subretinal hemorrhage
- Vitreomacular traction syndrome
- Myopic traction maculopathy
- Retinal detachment secondary to optic pit, and other optic nerve anomalies
- Transplantation of retinal photoreceptors or retinal pigment epithelium

#### Pediatric Retinal Disorders

- Retinopathy of prematurity
- Persistent hyperplastic primary vitreous
- Familial exudative vitreoretinopathy
- Giant retinal tears/dialysis
- Juvenile retinoschisis
- Juvenile rheumatoid arthritis
- Retinal detachment secondary to choroidal coloboma
- Retinal detachment in “morning glory” syndrome or optic nerve colobomas
- Gene therapy for treatment of retinal degenerations

#### Tumors

- Choroidal melanoma
- Complications of retinal angiomas
- Combined hamartoma of the retina and retinal pigment epithelium
- Intraocular lymphoma
- Diagnostic vitrectomy, fine needle aspiration

#### Uveitis

- Viral retinitis—cytomegalovirus infection, acute retinal necrosis
- Intraocular infections—bacterial, viral, fungal, parasitic
- Ophthalmomyiasis
- Inflammatory conditions—sarcoidosis, Behçet’s syndrome, uveal effusion
- Pars planitis
- Whipple’s disease
- Familial amyloidosis
- Hypotony

**Fig. 6.12.1** Typical small gauge vitrectomy cutters of 23-, 25-, and 27-gauge cutters showing the relative sizes of the cutting tips.

**Fig. 6.12.2** Small-Gauge Instruments Also Include Forceps and Scissors. Tips of the forceps have been designed to provide more delicate grasping of tissue (top), whereas scissors can be straight or curved to conform to the shape of the eye (bottom).

injection of gas. Otherwise, elevated intraocular pressure or an inadequate gas fill may result.

## GENERAL TECHNIQUES

Microincision vitrectomy uses instruments of 23-gauge,<sup>1</sup> 25-gauge,<sup>2</sup> or 27-gauge<sup>3</sup> caliber (Fig. 6.12.1) and has replaced standard 20-gauge vitrectomy for most cases in the hands of most surgeons. Microincision vitrectomy employs self-retaining microcannula ports, which are inserted transconjunctivally by using trocar needles. During insertion, the needles are directed at such an angle that a beveled self-sealing incision results. The cannulas are placed 3.5–4.0 mm posterior to the corneal limbus, depending on the phakic status of the eye. Usually the inferior cannula is connected to an infusion line to replace the vitreous removed with balanced saline. A vitreous cutter probe, and a fiberoptic light probe are inserted through the superior sclerotomy openings. “Valved” cannulas, which have a thin membrane covering the entrance of the cannula, are increasingly utilized so that fluid egress from the eye is limited during the procedure and turbulent flow and pressure oscillation in the eye are minimized. Additional light fibers of 2-gauge or 27-gauge (“chandelier” lighting) can be inserted through the pars plana to supplement the light from the fiberoptic probe or allow two instruments to be placed into the eye for bimanual dissection. An assortment of additional instruments, such as forceps, scissors, and laser probes, is also available for membrane manipulation (Fig. 6.12.2). Even the most complex vitrectomies can be done with smaller gauges, with 20-gauge instruments still required to remove dense lens fragments or foreign bodies. Most of the small-gauge incisions are

**Fig. 6.12.3** Wide-angle indirect contact lenses afford a view of much of the retina, here during air–fluid exchange. Inferiorly, a buckle anterior to the equator is visible.

self-sealing, but occasionally, a single transconjunctival suture is necessary to close a leaky opening.

A high-resolution surgical microscope is used to view the fundus during surgery. A plano-concave contact lens is used most commonly, but additional surgical viewing lenses (e.g., prism lenses, lenses of higher refractive index) have been developed to improve intraoperative visualization. Of increasing acceptance is the use of contact or noncontact wide-field or panoramic viewing systems based on the principles of binocular indirect ophthalmoscopic visualization (Fig. 6.12.3). Such systems offer an expanded visualization area and increased depth of focus but require that an image inverter be mounted on the microscope. Recently, systems using binocular video cameras placed onto the body of a surgical microscope have been developed for vitrectomy. The surgeon views a large surgical monitor with three-dimensional glasses and is able to perform the delicate surgical maneuvers required. Advantages for such an approach are that lower illumination is required, and ergonomically, the surgeon's neck and back are less prone to stress.

## SPECIFIC TECHNIQUES

### Lensectomy

Lensectomy is indicated when cataract prevents visualization of the fundus or when the lens is subluxated. Furthermore, the lens is removed if vitreoretinal traction located at or anterior to the vitreous base must be dissected, which is most frequently seen in proliferative vitreoretinopathy (PVR) and trauma. Ultrasonic fragmentation of the lens is usually approached from the pars plana with the lens equator entered by the fragmentation probe. If no IOL is to be placed, the capsule is excised completely by using the vitreous cutter or removed en bloc with forceps.

It has become increasingly common to combine standard phacoemulsification, using an acrylic foldable IOL, with vitrectomy.<sup>4</sup> This combined approach speeds the recovery time for stabilization of visual acuity.

### Vitreous Cutters

The vitreous cutting technology used is the guillotine cutter. This instrument, which comes in 20, 23, 25, and 27 gauges, consists of a round needle-like shaft with a small opening near the tip. Tissue is aspirated into the port and cut by an inner hollow sleeve that moves back and forth along the long axis of the probe. Currently, cutting speeds of up to 10000 cuts/min are attainable. Higher cutting speeds result in less traction on the tissue, and theoretically, fewer iatrogenic tears would occur when the probe is working near the surface of the retina. Higher cutting rates have also been introduced by modifying the inner cutting sleeve to have two openings so that with each stroke, the tissue is cut twice with one cycle. Enhancements, such as placing the port closer to the end of the probe or beveling the end of the probe, also allow the port to be placed closely to the tissue that is being cut (Fig. 6.12.4).

**Fig. 6.12.4** A vitreous cutter with a beveled tip can allow the port to be closer to the retinal surface. This is particularly useful in cases of proliferative diabetic retinopathy.

## Epiretinal Membrane Dissection

Two types of epiretinal proliferation are encountered:

- Fibrovascular proliferation, which contains neovascularization, most commonly seen in proliferative diabetic retinopathy (PDR).
- Nonvascular membranes, found in PVR and macular pucker.

In cases of PDR, the surgical goals are to separate the posterior hyaloid from the retinal surface peripherally and to remove the epiretinal proliferative tissue or release its tractional effects centrally and/or peripherally. Surgical techniques employed to remove the proliferative tissue are:

- Segmentation.
- Delamination.
- En bloc dissection.

The dissections are achieved by using microsurgical instruments. The smaller-gauge cutters are able to access small openings in the tissue planes and can be quite effective in removing layers of fibrovascular proliferation. Scissors that cut perpendicularly across fibrovascular tissue or scissors that have curved blades to cut between the retinal attachments of the proliferative tissue are available. The use of lit, multifunction instruments allows for bimanual delamination of tissue, which can be carried out more safely and with less bleeding. Attainment of the surgical objectives results in a stabilization of the retinopathy and vision.

Nonvascular ERMs are found in PVR and, in a less severe form, macular pucker. Such membranes may adhere strongly to the surface of the retina and are best removed by using end-gripping membrane forceps; a bimanual approach with the use of an illuminated membrane pick and forceps reduces the possibility of the formation of iatrogenic retinal tears.

It is recognized now that mechanical effects of the posterior hyaloid at the vitreous–retinal interface may result in macular hole formation and central visual loss. The actual structural changes within this layer of cortical vitreous that cause retinal pathology are unclear. A critical step in the surgical management is separation of the posterior hyaloid from the retina. After a central vitrectomy has been performed, the adherent layer of cortical vitreous at the vitreous–retinal interface is engaged and elevated by using the vitreous cutter. The posterior hyaloid is most adherent at the optic disc and at the macular region. After separation of the hyaloid, noted by observation of Weiss' ring, the vitreous layer can be excised out to the periphery.

## Intraoperative Tissue Staining

Because many preretinal tissues, such as the cortical vitreous, ERM, and internal limiting membrane, are transparent by nature, several chemicals can aid in their visualization during vitrectomy. Intravitreal indocyanine green (ICG) dye was first employed to stain the internal limiting membrane in order to facilitate peeling and complete removal. ICG is widely employed, especially for macular hole surgery. However, photosensitivity and the creation of deeper cleavage planes when peeling the internal limiting membrane have been observed. This has prompted the use of alternative stains, such as trypan blue for staining of ERM; brilliant blue for staining of the internal limiting membrane (Fig. 6.12.5); and triamcinolone, which appears to be particularly useful in highlighting cortical vitreous (Fig. 6.12.6).

**Fig. 6.12.5** Staining of internal limiting and epiretinal membranes, in this case with brilliant blue, can be particularly helpful in cases where poor and irregular pigmentation of the fundus make visualization challenging, in this case in a high myopic eye with tractional foveoschisis.

**Fig. 6.12.6** Cortical vitreous stains particularly well with triamcinolone, and this can aid in its complete and safe removal, as in this case of myopic foveoschisis.

## Perfluorocarbon Liquids

Perfluorocarbon liquids are useful as an intraoperative mechanical tool. The various perfluorocarbon liquids currently used in vitreous surgery have different physical and optical properties. Perfluoro-*n*-octane, because of the better visibility it allows, low viscosity, and high vapor pressure, is the most commonly used of these. Giant retinal tears with large, inverted posterior flaps can be repositioned easily into their normal anatomical position, which allows for the successful management of this condition without the use of special equipment to rotate the patient intraoperatively.<sup>5</sup>

In PVR, as perfluorocarbon liquid flattens the posterior retina, retinal folds are opened and allow for traction and visualization of additional membranes. A posterior retinotomy for internal drainage of subretinal fluid is no longer necessary. The retina is stabilized as membrane dissection proceeds, and large retinotomies, when necessary, can be carried out more safely.

Other applications of perfluorocarbon liquids are to float dislocated lens fragments or dislocated IOLs anteriorly, to provide intraocular hemostasis by localization of bleeding, and to express liquefied subretinal blood from under the retina.

## Endophotocoagulation

Laser photocoagulation is applied around retinal breaks and circumferential retinotomies; in general, 2–3 rows of treatment are adequate. In more advanced cases of retinal detachment, such as PVR, laser spots may be placed contiguously in two or three rows on the anterior slope of the scleral buckle. In PDR, scatter photocoagulation is applied to areas of peripheral ischemia, thus reducing the risk of neovascular glaucoma.

## Gas and Silicone Oil Tamponade

The final step in vitreous surgery is to decide whether it is necessary to fill the vitreous space by using a tamponade agent. An automated air-infusion pump is used to perform the fluid–air exchange. A flute needle is used actively or passively to aspirate the intraocular fluid as air is infused through the infusion line.

In cases where no retinal detachment exists, a bubble tamponade may be unnecessary; but in some cases, air is used to smooth out retinal folds or to allow visualization through a hemorrhagic medium postoperatively. In macular hole surgery, a longer-lasting gas bubble is useful as its buoyant force may help to close the hole. When retinal detachment is present, the subretinal fluid must be evacuated to achieve a complete fill with gas and ensure that the retina flattens without posterior folds. Perfluorocarbon liquid may be injected to flatten the retina up to the level of peripheral retinal breaks—the posterior subretinal fluid is expressed anteriorly. Internal drainage of the remaining subretinal fluid is accomplished by placement of the aspirating needle through the retinal break as air enters the eye. The descending air bubble flattens the anterior retinal detachment and forces the anterior subretinal fluid through the retinal break. When the subretinal fluid has been aspirated completely or nearly completely, the perfluorocarbon liquid may be removed.

The type of gas used is dependent on the individual clinical situation.<sup>6</sup> In eyes with simple retinal detachment, the role of the gas bubble is to allow adequate time for the chorioretinal adhesion from laser treatment to form. Usually, air or sulfur hexafluoride, which persists for 10–14 days, may be used. For more complex retinal detachments, such as PVR, trauma, and giant retinal tears, a longer-lasting gas bubble is usually required. Perfluorohexane or perfluoropropane gases are chosen frequently in these situations.

Silicone oil tamponade may also be used as a long-term tamponade agent. This clear viscous liquid, which is immiscible with water, replaces the vitreous. Its surface tension and mild buoyant force mechanically hold the retina against the choroid. The advantage of silicone oil is that the patient has vision through the oil bubble and that extensive prone-head positioning (required with gas bubbles) is unnecessary. However, silicone oil may require surgical removal months after the retina has been reattached. The results of a multicenter, randomized clinical trial, in which the use of perfluoropropane gas was compared with the use of silicone oil for the treatment of severe PVR, found no statistically significant difference in the final retinal reattachment rate between the two modalities.<sup>7</sup>

## COMPLICATIONS

Many of the potential complications of vitreous surgery may be realized during the later postoperative period. The rate of complications has decreased gradually as improvements in technology have been introduced. However, experience, surgical skill, and training are also significant factors that can reduce the rate of complications. The more widely described intraoperative and postoperative complications encountered with vitreous surgery are given in [Box 6.12.2](#).

## OUTCOMES

The introduction of new surgical techniques and instrumentation and improved knowledge of the pathophysiology of abnormal vitreoretinal structural changes have resulted in a steady improvement in the anatomical and visual results of vitreous surgery. Some of the results reported for the most common indications of vitrectomy are given in [Table 6.12.1](#) and represent significant advances in the surgical treatment of retinal disorders.

TABLE 6.12.1 Surgical Outcomes in Vitreous Surgery

Vitreoretinal Disorder	Outcome
Diabetic vitreous hemorrhage	89% improvement with clear vitreous <sup>8</sup>
Diabetic traction retinal detachment	66%–95% retinal reattachment rate <sup>9</sup>
Proliferative vitreoretinopathy	94% final retinal reattachment rate <sup>10</sup>
Giant retinal tears	96% final retinal reattachment rate <sup>5</sup>
Macular pucker	80%–90% visual improvement by two or more Snellen lines <sup>11</sup>
Idiopathic macular hole	85% visual improvement by two or more lines <sup>12</sup>
Dislocated lens fragments	68% final visual acuity 20/40 (6/12) or better <sup>13</sup>
Retinal detachment	70%–90% primary reattachment rate <sup>14</sup>

BOX 6.12.2 Potential Complications of Vitreous Surgery

Intraoperatively

- Corneal epithelial defect
- Posterior retinal breaks
- Peripheral retinal breaks
- Choroidal hemorrhage (rare)

Postoperatively

- Retinal breaks
- Rhegmatogenous retinal detachment
- Elevated intraocular pressure (multiple potential causes)
- Neovascular glaucoma
- Angle-closure glaucoma
- Inflammatory debris
- Corticosteroid response
- Overfilling with gas
- Anterior hyaloidal fibrovascular proliferation
- Fibrin deposition in the anterior chamber (not rare, especially in individuals with diabetes)
- Progressive nuclear sclerosis (almost universal in phakic eyes)
- Corneal decompensation
- Hypotony
- Endophthalmitis (incidence 1 in 2500)

# Intravitreal Injections and Medication Implants

6.13

*Ryan W. Shultz, Maya H. Maloney, Sophie J. Bakri*

**Definition:** Intravitreal injections and implants, most often administered as an office procedure, are a safe, effective, and common method of delivering medication locally to the eye.

## Key Features

- Topical anesthesia is usually sufficient.
- Sterile technique is used.
- Small-gauge needles (30-gauge or smaller) can be used for intravitreal injections.
- Effective method to deliver antivascular endothelial growth factor medications, corticosteroids, antibacterial and antiviral agents, air, and gas.

## Associated Features

Complications include:

- Infectious endophthalmitis.
- Sterile inflammation.
- Retinal tears.
- Vitreous hemorrhage.
- Cataract.
- Intraocular pressure elevation; intraocular pressure should be monitored when injecting larger volumes of medication and in patients with glaucoma.
- Different techniques of insertion for multiple platforms of sustained-release implants.

## INTRODUCTION

The office delivery of medication directly into the vitreous cavity via injection or implant has become commonplace in ophthalmology. This method allows for higher concentrations of medication in the eye with less systemic absorption compared with other methods of administration. In 1911, the injection of air into the vitreous cavity for retinal detachment (RD) repair was initially reported, followed by reports of the injection of penicillin for endophthalmitis in 1947.<sup>1</sup> Fomivirsen (Vitravene; Isis Pharmaceuticals) was the first medication approved by the U.S. Food and Drug Administration (FDA) for intravitreal use in 1998 for the treatment of cytomegalovirus (CMV) retinitis. Pegaptanib (Macugen; OSI Pharmaceuticals), ranibizumab (Lucentis; Genentech), and aflibercept (Eylea; Regeneron Pharmaceuticals) have all since been FDA approved for use in exudative age-related macular degeneration (AMD),<sup>2</sup> and bevacizumab (Avastin; Genentech) is commonly used off-label to treat many forms of choroidal neovascularization and macular edema. The introduction of these vascular endothelial growth factor (VEGF) inhibitors for the treatment of common ocular conditions, such as diabetic retinopathy and exudative AMD, has resulted in a critical need for the ophthalmologist to fully understand the process of performing intravitreal injections.

## PREINJECTION PREPARATION

Patients for whom intravitreal injection is recommended should be evaluated prior to injection for any signs of ocular infection (Box 6.13.1). Overt, active blepharitis should be treated before injection to decrease the bacterial

## BOX 6.13.1 Intravitreal Injection Technique Recommendations

### Preinjection

- External ocular examination, visual acuity, and intraocular pressure check
- Informed consent form
- Anesthesia (topical or subconjunctival)
- Topical povidone-iodine (5% for the ocular surface, 10% for the lids and lashes)

### Injection

- Surgical pause confirming the correct patient, laterality, and medication
- Surgical gloves (sterile or nonsterile)
- Placement of sterile lid speculum or manual lid retraction
- Caliper to measure 3.5–4.0 mm posterior to limbus in preferred quadrant
- 5% povidone-iodine to injection site
- Penetration with small gauge needle through conjunctiva and sclera (perpendicular to surface or “tunneled”)
- Slow, steady injection of medication
- Sterile cotton tip applicator at injection site to prevent reflux as needle is removed
- Removal of speculum (if used)
- Maintain sterility of instrument surfaces that contact the eye, prior to injection

### Postinjection

- Irrigation of ocular and periocular surfaces with balanced salt solution
- Confirmation of central retinal artery perfusion (visual acuity or direct visualization)
- Intraocular pressure (IOP) check with administration of IOP-lowering medication, if indicated
- Lubricating drops or ointment at end of procedure
- Instruction sheet with information on injection procedure as well as emergency contact number

load, which may increase the risk of infection.<sup>3</sup> Patients with bacterial or viral conjunctivitis should be treated appropriately to manage infection and should have their injection rescheduled. Prophylactic preinjection antibiotics have not been shown to decrease the conjunctival bacterial load compared with application of 5% povidone-iodine prior to injection.<sup>4</sup> There is also concern that routine use of prophylactic antibiotics will increase resistant strains of bacteria on the conjunctival surface without decreasing rates of endophthalmitis.<sup>5</sup> As with any surgical procedure, all patients should sign an informed consent form after being explained the risks, benefits, and alternatives to injection.

## Pupillary Dilation

Evaluation of central retinal artery perfusion following an intravitreal injection may be required in patients with a history of elevated intraocular pressure (IOP). This may also be beneficial in patients who are receiving larger doses of medication or multiple medications.<sup>6</sup> Dilation may not be required in patients presenting only for injection and who have stable visual acuity and unchanged visual symptoms.

## Anesthesia

Topical, subconjunctival, and peribulbar routes of local anesthesia have all been employed for intravitreal injections with similar levels of pain control.<sup>7</sup> Use of topical 0.5% proparacaine or 0.5% tetracaine drops provide adequate analgesia with minimal side effects.<sup>8,9</sup> A cotton pledget soaked with 4% lidocaine can also be applied to the conjunctival surface. Injection of subconjunctival 2% lidocaine is effective as well but may be associated with subconjunctival hemorrhage, which could be of cosmetic concern to the patient.<sup>6</sup> Topical lidocaine gel is another alternative,<sup>10</sup> but theoretical concerns that the gel may prevent the bactericidal effect of the povidone-iodine have been raised.<sup>11</sup> These are several available options, and different patients may respond more favorably to different forms of anesthesia.

The majority of patients receive their injections in the clinic, with very low complication rates and appropriate analgesia.<sup>7,12</sup> Furthermore, patients being treated for endophthalmitis may have different anesthesia requirements because of their significant inflammatory response.

## Antisepsis

Povidone-iodine is recommended for preinjection antisepsis and has been shown to decrease the rate of endophthalmitis in cataract surgery.<sup>3,13</sup> It is bactericidal and has rapid cytotoxicity.<sup>14</sup> The periocular lids and lashes can be cleaned with 10% povidone-iodine. Cleaning should begin at the lashes and move peripherally so as not to introduce bacteria to the ocular surface. Gentle cleaning of the lid margin is recommended to prevent discharge of bacteria from the meibomian glands onto the ocular surface, which may otherwise result from vigorous cleaning.<sup>3</sup> The ocular surface is treated with 5% povidone-iodine, which reduces ocular irritation but still has a bactericidal effect.<sup>15,16</sup> There have been no reported cases of anaphylaxis to povidone-iodine related to ophthalmic use.<sup>17</sup> One may consider referral for skin testing by an allergy specialist for patients reporting any allergies. Allergic contact dermatitis and surface irritation are side effects of povidone-iodine that may result in postinjection discomfort.<sup>18</sup> An endophthalmitis rate of 9.4% has been associated with the failure to use povidone-iodine for injections in patients with self-reported allergies.<sup>19</sup> Chlorhexidine is effective at reducing surgical site infections, and the aqueous form can be used to prepare the ocular surface.<sup>19,20</sup>

Use of a sterile lid speculum or manual lid retraction is recommended to prevent contact between the tip of the needle and the patient's lids or lashes. However, this may compress the meibomian glands, resulting in discharge of their contents onto the ocular surface, so an additional application of 5% povidone-iodine may be given prior to injection. The use of gloves (sterile or nonsterile) is considered essential; however, the use of drapes or gowns is not.<sup>3</sup>

Minimal talking or the use of masks after the preparation of the ocular surface is encouraged to prevent airborne contamination by *Streptococcus*.<sup>3</sup> There is theoretical concern that airborne droplets may settle on the exposed needle prior to injection.<sup>21</sup> Maintaining silence may be difficult, however, in cases where patients require further instruction after sterile preparation.

## INJECTION

The needle used for injection need be no larger than 30-gauge for a routine injection of medication or gas. Use of a smaller-gauge needle may reduce procedural discomfort in patients.<sup>22</sup> The force required to penetrate the sclera is almost doubled when using a 27-gauge needle compared with a 30- or 31-gauge needle.<sup>23</sup> Needle length should be 5/8 of an inch or shorter to prevent globe trauma.<sup>3</sup> The majority of retinal specialists surveyed in 2010 reported using a 30-gauge needle for injections of bevacizumab and ranibizumab, and a 27-gauge needle for triamcinolone.<sup>24</sup> Triamcinolone can precipitate within the syringe and clog a needle smaller than 30-gauge. Separate needles should be used to remove the medication from the vial (usually a filter needle) and to perform the actual injection (30–32 gauge). This helps prevent both contamination and dulling of the needle.

The injection is given through the pars plana approximately 3.5–4.0 mm posterior to the limbus.<sup>3</sup> Injections are commonly performed in the inferotemporal and superotemporal quadrants. The quadrant of injection may be influenced by the indication for injection or other factors. For example, injecting an opaque corticosteroid superiorly may initially obscure the visual axis more compared with an inferiorly administered injection. Similarly, a patient with a large inferotemporal retinoschisis cavity may benefit from having the injection given in another quadrant.

The traditional injection method involves inserting the needle perpendicular to the sclera in a single plane to penetrate the globe, although tunneling methods have also been described.<sup>25</sup> The final needle direction should always be toward the center of the eye to prevent damage to other intraocular contents.<sup>3</sup>

The medication should be injected in a slow, steady manner to prevent a sudden flux through the vitreous cavity because this may disrupt vitreoretinal adhesions. A sterile cotton tip applicator may be used to prevent reflux after needle removal.<sup>26</sup> Injection of larger volumes of medication (e.g., for endophthalmitis) may require removal of aqueous or vitreous humor to prevent IOP elevation.

## POSTINJECTION

The use of topical antibiotics following intravitreal injections had previously been a common practice but is no longer recommended.<sup>3</sup> Recent clinical trials have demonstrated that postinjection topical antibiotics may not be required for patients undergoing routine intravitreal injections of anti-VEGF or corticosteroid medications.<sup>27</sup> Routine use of topical fluoroquinolones after injections has been shown to increase rates of antibiotic resistance of conjunctival flora.<sup>28</sup>

The ocular and periocular surfaces should be irrigated to remove the povidone-iodine. Lubricating drops or ointment may be placed on the eye to alleviate ocular discomfort associated with the povidone-iodine preparation.

IOP elevation is common after intravitreal injection but remains below 35 mm Hg in the majority of patients. Patients with glaucoma may be more susceptible to IOP elevation. IOP can be monitored following injection and topical medications given, if needed.<sup>3,6</sup> Anterior chamber paracentesis should not be performed routinely after each injection to lower IOP.<sup>3</sup> However, injection of larger volumes or multiple medications may require paracentesis. The presence of at least light perception vision suggests that the central retinal artery is perfused, but the most reliable method to confirm perfusion is direct visualization with the indirect ophthalmoscope.<sup>29</sup>

Prior to leaving the office after the injection, the patient should be counseled regarding ocular care at home and about symptoms that would require evaluation prior to the next scheduled visit. Appropriate education regarding expected side effects from the povidone-iodine preparation and intravitreal injection, versus symptoms of injection complications, may help avoid unnecessary concern or additional visits (Table 6.13.1). Providing an instruction sheet in large print with the above information, as well as a 24-hour contact number, is beneficial.

## COMPLICATIONS

### Endophthalmitis

Endophthalmitis is a potentially devastating complication that may result in poor visual outcomes. A systematic review of data from approximately 40 years and including >14,000 intravitreal injections reported that the prevalence of endophthalmitis was 0.2% per injection. This review included injections for a wide range of diagnoses, and there was a higher prevalence (0.6% per injection) of endophthalmitis after injection of triamcinolone acetonide. All other therapeutics had a risk of 0.1% per injection.<sup>30</sup> A more recent review of pooled data from 20 case series, including 510 396 anti-VEGF injections, indicated that the prevalence of endophthalmitis was 0.028%, or approximately 1 of every 3544 injections. One case series included in the review reported no cases of endophthalmitis after 15,444 injections.<sup>31</sup> *Staphylococcus* is the most common organism associated with endophthalmitis, and *Streptococcus* is a known cause of endophthalmitis that has been suggested to originate from nasopharyngeal droplets.<sup>12</sup> Vitreous wick syndrome is a theory that suggests vitreous incarceration into a scleral wound may act as a conduit for bacteria. A tunneled injection,<sup>25</sup> smaller-gauge needle,<sup>32</sup> and placement of a sterile cotton tip applicator over the injection site may prevent this from occurring.<sup>33</sup>

TABLE 6.13.1 Intravitreal Injection Complications

Endophthalmitis	Retinal pigment epithelium tear
Retinal vascular occlusion	Retinal tear or detachment
Elevated intraocular pressure	Subconjunctival hemorrhage
Corneal abrasion	Vitreous hemorrhage
Cataract progression	Inflammation

## Hemorrhage

Ocular hemorrhage is another possible complication of intravitreal injections. Subconjunctival hemorrhage may occur as a result of laceration of subconjunctival or episcleral vessels. Vitreous hemorrhage may occur if the needle contacts the ciliary body or the retina or in patients with abnormal neovascularization, such as in those with proliferative diabetic retinopathy. Patients on warfarin in the MARINA study did not have significant ocular hemorrhagic complications, and discontinuation of systemic anticoagulation is not recommended.<sup>3,34</sup> Discontinuation of antithrombotic or anticoagulation medications may increase the risks of thromboembolic or cerebrovascular events and should only be done in coordination with a patient's primary care physician.<sup>35</sup>

## Intraocular Pressure Changes

Immediate, transient elevations in IOP following intravitreal injections are a known side effect,<sup>6</sup> but sustained elevation in IOP has also been reported. Patients receiving repeated injections of anti-VEGF medications have been shown to have elevated IOP readings over several visits.<sup>36–39</sup> Ocular hypertension is a known side effect of corticosteroids, but this mechanism of sustained IOP elevation is related to the corticosteroid rather than to the injection itself.<sup>40</sup> Hypotony has been reported after uncomplicated intravitreal injections but was believed to be secondary to ciliary body toxicity from the injected medication.<sup>30</sup>

## Retinal Pigment Epithelium Tears

Retinal pigment epithelium (RPE) tears have been reported following intravitreal injections of anti-VEGF medications.<sup>41–44</sup> However, patients receiving injections for exudative AMD in the ANCHOR, MARINA, and PIER studies of ranibizumab did not have an increased prevalence of RPE detachments compared with controls.<sup>45</sup>

## Retinal Tears and Detachments

Retinal tears or detachments may be associated with intravitreal injections. The incidence of RD was 1 per 7188 injections in nearly 36000 patients receiving anti-VEGF medications.<sup>46</sup> A large review reported the incidence of RD to be 0.9% per injection. However, this included patients with ocular conditions that predispose to RD, such as CMV retinitis and diabetic retinopathy.<sup>30</sup>

## Other Complications

Uveitis has been reported following intravitreal injections, but it is believed that the inflammatory reaction is secondary to the injected medication rather than to the injection itself. Progression of cataract in patients with phakia has been reported, in addition to rare instances of trauma to the lens or lens capsule, which may also result in cataract formation.<sup>30</sup> Tiny silicone oil droplets following intravitreal injections have been reported in the vitreous cavity. They are believed to be from the silicone lubricant in the needles or syringes and have no adverse side effects.<sup>47</sup> Corneal abrasions may occur with removal of the lid speculum or as a result of the toxic effects of the anesthetic and povidone-iodine on the ocular surface. Retinal vascular occlusions have also been reported following intravitreal injections.<sup>30</sup> When complications do occur, the physician should try to determine whether it was from the injection procedure or the injected medication.

## OTHER CONSIDERATIONS

Patients with bilateral ocular disease requiring intravitreal injections may have them performed on the same day<sup>48</sup> or on separate days. Same-day bilateral injections may be especially beneficial for patients in whom transportation to office visits is difficult and long-term bilateral injections are anticipated. Nearly 57% of retina specialists in the United States reported giving same-day bilateral intravitreal injections for exudative AMD in 2016.<sup>49</sup> These patients should be counseled on the possible risk of bilateral ocular complications after the injections. Endophthalmitis has been associated with contaminated batches of bevacizumab from compounding pharmacies.<sup>50</sup> To reduce the risk of medication contamination when injecting a compounded off-label medication, ideally, each eye should be treated from a different batch of compounded medication from the same compounding

pharmacy, or medications obtained from different compounding pharmacies should be used.

## IMPLANTS

Intravitreal implants that allow for long-term release of medication are also being used in the management of retinal diseases and uveitis. The search for delivery systems and medications with longer durations of efficacy may result in intravitreal implants becoming a more common treatment modality.

A sustained-release 0.7 mg dexamethasone implant (Ozurdex; Allergan) has been FDA approved for use in macular edema secondary to retinal vein occlusions, diabetic retinopathy, and noninfectious posterior uveitis.<sup>2</sup> The implant comes loaded in a disposable injector with a 22-gauge needle. It is injected through the pars plana, similar to an intravitreal injection.<sup>51</sup> Because of the larger-gauge needle, patients may have increased requirements for anesthesia (e.g., subconjunctival anesthetic injection) compared with a standard intravitreal injection with a smaller-gauge needle (which may be done under cover of topical anesthesia). This implant, which is biodegradable, has been shown to have clinical efficacy for several months.<sup>51</sup> Sustained-release 0.2 µg/day fluocinolone acetonide implant (Iluvien; Alimera Sciences) is FDA approved for the treatment of chronic diabetic macular edema. It was shown to have visual benefit for up to 3 years, with primary adverse events, including IOP elevation and cataract formation.<sup>52</sup> This nonbiodegradable implant is inserted through a 25-gauge needle.<sup>53,54</sup> Another corticosteroid implant, 0.59 mg fluocinolone acetonide (Retisert; Bausch and Lomb), is also approved for use in noninfectious posterior uveitis. This fluocinolone acetonide implant has clinical efficacy for up to 3 years and is also associated with elevated IOP and cataract formation.<sup>55</sup>

A ganciclovir implant (Vitrasert; Bausch & Lomb) is available and has been shown to decrease progression of CMV retinitis.<sup>56</sup> Placement of both 0.59 mg fluocinolone acetonide and ganciclovir implants is performed in the operating room under cover of local (peribulbar or retrobulbar) or general anesthesia. After creating a small opening in the conjunctiva, the implant is placed into the vitreous cavity through a sclerotomy wide enough to allow insertion of the implant into that area. The implant is then sutured in place at the sclerotomy, and the wounds are closed. Any prolapsed vitreous is removed.<sup>57</sup> These implants are not biodegradable and remain in the eye.

## CONCLUSIONS

As new developments in medications and medication delivery become available, the ophthalmologist will have to continue to evaluate the safest and most efficacious method of performing intravitreal injections to treat ocular disease.

# Progressive and “Stationary” Inherited Retinal Degenerations

6.14

Catherine A. Cukras, Wadih M. Zein, Rafael C. Caruso, Paul A. Sieving

## Definition of Progressive Inherited Retinal Degenerations:

Retinitis pigmentosa and the related rod-cone and cone-rod dystrophies constitute a broad set of disorders that generally result in progressive visual dysfunction secondary to loss of photoreceptors.

## Key Features

- Night blindness.
- Visual field constriction.
- Progressive photoreceptor dysfunction and death.
- Loss of rod and cone electroretinography (ERG) responses.
- Clinical degeneration of the outer retina.
- Intraneural retinal “bone-spicule” pigment.

## Associated Features

- Poor correlation between acuity and extent of “tunnel vision”.
- Retinal arteriolar narrowing.
- “Waxy nerve pallor” from reactive gliosis.
- Posterior subcapsular cataracts in middle age.
- Progressive chorioretinal atrophy.
- Frequently, but not always, a family history.
- Associated systemic abnormalities uncommon but important.

## Definition of “Stationary” Inherited Retinal Degenerations:

“Stationary” retinal degenerations are stable in comparison with, and less progressive than, most forms of retinitis pigmentosa (RP), even though there is often some change over time.

## Key Features

- Poor night vision present since birth.
- Fundus appearance may be normal or abnormal.

## Associated Features

- The pathology has an anatomical locus, as revealed by visual function tests.
- Molecular genetic studies suggest pathogenetic mechanisms in certain types.

## PROGRESSIVE DIFFUSE/PANRETINAL DEGENERATIONS

### Introduction

The term *retinitis pigmentosa* (RP) encompasses a set of diverse hereditary disorders that affect the photoreceptors and retinal pigment epithelium (RPE) diffusely across the entire fundus but begin with initial geographical involvement in either the periphery or the macula. These conditions typically, but not always, progress over many years to an advanced stage

and result in global reduction or loss of vision. As a group, the majority of forms of RP lead initially to death of the rod photoreceptors, which impairs vision in dim light and causes loss of peripheral vision, and later involves cones as the symptoms progress leading to “tunnel vision.” However, some of the allied forms primarily cause cone photoreceptor loss and initially manifest with a reduction in central visual acuity.

Such conditions are determined genetically, and all genetic patterns of inheritance are represented. In many cases, a patient represents an isolated case with no known affected relatives, which makes a genetic etiology less obvious and must be differentiated from acquired etiologies, such as inflammatory or infectious retinal insults. The possibility and availability of genetic diagnosis is much higher than ever before, and identification of the various defects within the abnormal genes that result in these conditions is possible. New treatment options are being tested, and others are anticipated in the years ahead because of a new understanding of the pathophysiology of the disease.

The approach to the patient involves initial categorization of the degeneration into either a rod-cone disease or cone-rod disease, two conditions that carry different prognoses. Further subtyping of the disease provides even better information about prognosis. Rod-cone degeneration is typically more severe—the long-term prognosis is loss of most or all vision by later years. Cone-rod degeneration affects central vision quite early and peripheral vision only later. Because the human retina has 120 million rods and only 6 million cones, it may function well without cones, as exemplified by achromatopsia. The prognosis in cone-rod dystrophy is good for at least some future vision, even though central vision is jeopardized. A review of the patient’s symptoms and retinal function studies, particularly visual field testing and electroretinography (ERG), are required to differentiate rod-cone from cone-rod degenerations.

## Epidemiology and Pathogenesis

Familial retinal degeneration with intraneural retinal pigmentation was described as early as 1855 by Donders.<sup>1</sup> It is now understood that most cases have a genetic basis<sup>2</sup> and involve photoreceptor cell death through apoptosis. No racial or ethnic predisposition exists. Men may be affected slightly more than women because of X-linked conditions.

The term *retinitis pigmentosa* refers to a broad category of genetically heterogeneous diseases, which includes many different forms of primary photoreceptor abnormalities—some affect rods first and cones later (termed *rod-cone dystrophy*) or the reverse (termed *cone-rod dystrophy*). The prevalence of primary photoreceptor degeneration is in the range 1:3000–1:5000.<sup>3</sup> The carrier state for recessive retinitis pigmentosa is approximately 1:100, based on the prevalence of recessive retinitis pigmentosa.<sup>4</sup> These numbers are approximate because of the complexity of the many different forms of RP now identified by gene cloning. In most cases, these diseases are thought to be simple Mendelian traits that result from DNA alteration in single genes.

### Rod-Cone Dystrophy

Rod-cone dystrophy manifests clinically with typical RP and affects the rod photoreceptors earlier and more severely than it does the cone photoreceptors. Severe cone involvement occurs in the end stage of the disease, when total vision loss ensues. The key features of the rod-cone type of disease are progressive night blindness and visual field constriction, which become more severe as more rods die, leading to cone loss. The appearance of midperipheral ring scotomas during progressive stages of visual field loss is not uncommon. Typically, both eyes are affected similarly.

Visual acuity is initially affected minimally and typically remains near to 20/20 (6/6) for many years despite progressive field loss to severe tunnel vision. Careful history taking frequently reveals some night blindness, even in early-stage rod-cone disease. Symptoms of typical RP include prolonged dark adaptation. However, many patients with RP are able to drive at night on well-lit streets. Patients complain of problems in dimly lit restaurants and theaters and are symptomatic when they come indoors from bright sunlight. By the midstage of the disease, visual field constriction occurs. Patients may appear clumsy because they collide with a door frame or a friend who walks alongside because of unrecognized tunnel vision. End-stage rod-cone disease results in loss of both peripheral vision and central vision. Many patients have only barely functional central vision by late middle age and lose all vision later. However, the changes occur slowly, and the young patient may be reassured that some vision is most likely to remain for many years or decades, even though the long-term prognosis is grim. Glare sensitivity to bright light occurs in end-stage rod-cone dystrophy, when the diseased cones saturate in bright light.

The functional profile of early-stage rod-cone dystrophy is shown in Fig. 6.14.1. The rod ERG amplitude loss is worse than that for cones (light-adapted: single flash and 30 Hz flicker). Goldmann visual fields are still relatively large with the large V4e target but considerably constricted to the small I4e target—such disparity between the ratio of field area with the V4e versus I4e targets is typical for rod-cone dystrophy. Tests of dark-adapted thresholds show 1–3 log units of rod sensitivity loss, which equates with 10–1000 times more light required to see at night. The disease does not act uniformly across the retina, and rod threshold should be tested at multiple points of vision to give a sensitivity profile across the central and peripheral vision.

As visual fields constrict further, even to the large V4e target, dark-adapted thresholds become worse because only cones remain to mediate vision, even in dim light. At this stage, the patient suffers from

severe night blindness. With time, the cone ERG responses deteriorate further until eventually both the rod and cone responses are reduced profoundly, and all ERG responses are termed “nonrecordable.” By this time, visual acuity is typically less than 20/40 (6/12), color discrimination is impaired, and fields are greatly constricted.

Cone-Rod Dystrophy

Patients with cone-rod dystrophy complain of poor acuity, reduced color vision, and glare sensitivity to bright sunlight.

Particularly in the early stages, the fundus may appear normal, with minimal diffuse retinopathy and normal vessels and disc. Visual fields initially remain full with the Goldmann V4e target but may be constricted slightly with the I4e target. It is more likely that at least some peripheral vision is retained in patients who have cone-rod dystrophy as opposed to those who have rod-cone dystrophy. ERG shows that cone-mediated responses (30 Hz flicker and photopic single flash responses) are reduced proportionally more than the dark-adapted rod b-wave (see Fig. 6.14.1). Although the rod b-wave amplitudes may be subnormal technically, rod dark-adapted threshold sensitivity remains nearly normal when tested using a Goldmann-Weekers dark adaptometer after 45 minutes in the dark. The combination of ERG and psychophysical rod threshold tests is the best way to diagnose cone-rod dystrophy. Patients who have the least rod involvement carry the best prognosis for intermediate-term vision. At the other end of the prognosis spectrum are rare patients who develop a central scotoma early in life; the field defect enlarges gradually but relentlessly toward the periphery, with practically total visual loss by late middle age. These patients usually receive the diagnosis of “macular degeneration” in childhood; the condition has been termed “inverse retinitis pigmentosa” because pigment spicules are more abundant in the central retina than in the midperiphery. Infrequently, a patient with cone-rod dystrophy has an essentially normal rod but a very reduced cone on ERG and is considered to have “cone dystrophy.” Such patients have a good prognosis for vision into later age. Some patients with cone-rod dystrophy are first symptomatic after age ≥50 years and may progress quickly to considerable vision loss.<sup>5</sup> Such patients are a diagnostic challenge because of the later age at presentation; initially, ERG results may be marginally normal, but the results of repeat ERGs after 6–12 months progress to subnormal.

Diagnosis and Ancillary Testing

For diagnosis, visual function tests are an important adjunct to retinal examination. Tests may also help identify correctly the clinical subtype of the disease. Accurate subtyping provides the basis for counseling about expectations for school and career choices, for the provision of genetic information to the extended family, and for potential treatment.

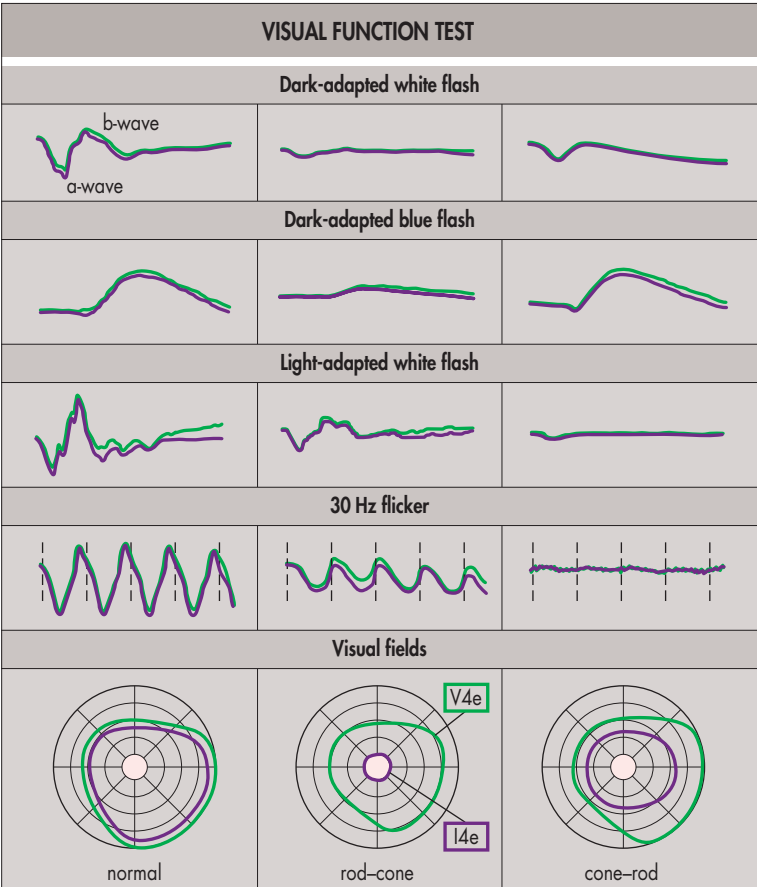

The history can be helpful. Complaints of “night blindness” may indicate total lack of vision in very dim light or diminished acuity as ambient light dims. Tunnel vision may be suggested by recent automobile accidents or clumsiness in the narrow spaces of elevators or doorways. Any family history of slowly progressive unexplained vision loss must be sought.

Electroretinography

Full-field (Ganzfeld) electroretinography (ERG) is quite sensitive to even mild photoreceptor impairment. Rod b-wave amplitudes are reduced in the earliest stages of disease when the retina may appear clinically normal and vision complaints are minimal. For the diagnosis of genetically at-risk younger patients who have otherwise minimal retinal findings, ERG is essential. ERG helps in the diagnosis of the disease in relatives when a retinitis pigmentosa pedigree is established.

Initially, ERG is used to test the rod system by testing with a dim flash after 30 or more minutes in the dark (“scotopic ERG”). The cone system is tested by using single, bright flashes superimposed on a bright background that suppresses activity of rods (“photopic ERG”) and also using a 30-Hz flicker to which cones respond but rods do not. Many complex and analytical schemes of ERG analysis are employed in special circumstances, but the most useful initial measures of ERG abnormality will be discussed below.<sup>6</sup> Scotopic (dark-adapted condition, rod-driven) and photopic (light-adapted, cone-driven) b-wave amplitudes are key in that they provide the first index of disease severity and help differentiate rod-cone from cone-rod disease.

- Scotopic b-waves reduced by 50% or more—this indicates progressive disease rather than a variant of “stationary” disease.
- Early cone system disease—this frequently reduces the amplitudes of 30-Hz flicker before photopic b-wave responses to single flashes.

**Fig. 6.14.1 Visual Function Tests.** For normal subjects, dark-adapted rod a- and b-waves result from bright, white flashes and, primarily, b-waves from dimmer blue flashes; cone responses are elicited by a single, light-adapted, white flash (a- and b-waves) and by 30-Hz flicker. For patients with rod-cone dystrophy, rod responses are reduced proportionally more than cone responses. For patients with cone-rod dystrophy, major losses in light-adapted and 30-Hz responses occur, with relative preservation particularly of the rod b-wave, to dim, dark-adapted, blue flash. Goldmann visual field tests using the small I4e target show major tunnel vision in patients with rod-cone dystrophy.

- Delayed flicker implicit time (from flash to response peak)—this is a highly sensitive measure of abnormality,<sup>7</sup> and implicit times may be prolonged even with normal flicker amplitude; implicit times are very robust and relatively immune to artifacts caused when the patient squeezes on the ERG contact lens electrode (which reduces flicker amplitude but does not change timing).
- Photopic oscillatory potentials (high-frequency wavelets of small amplitude that originate in the proximal retina)—these are generally reduced earlier or to a greater degree than the photopic, single-flash b-wave, and oscillatory potentials may be reduced in retinal vascular diseases.
- Relative preservation of the scotopic a-wave amplitude (from rod photoreceptors) but reduced scotopic b-wave (from signaling by second-order bipolar cells)—this is called an “electronegative” ERG wave-form and is highly suggestive of congenital stationary night blindness (CSNB) or X-linked juvenile retinoschisis.<sup>8,9</sup> In these cases, the ERG change indicates faulty synaptic signaling from rods to bipolar cells, deficient bipolar responsivity, or Müller cell disease.
- Broad and flat bottom trough to the photopic a-wave—this is highly suggestive of CSNB.
- The full-field ERG reflects global retinal activity and is insensitive to macular scars; thus, it does not correlate with visual acuity determined solely by foveal function.

### Monitoring Disease Progression

After some time, the ERG is repeated for the following reasons:

- Confirmation of the diagnosis.
- Determination of the rate of progression.
- Monitoring of the effects of therapy, such as vitamin A administration or other.
- Provision of objective information about progression, to help the patient cope with a disease that causes vision loss.

ERG may be repeated 1–2 years after the first test just to confirm the findings, or serial yearly tests may be used to estimate progression. Exceptionally rapid cone ERG loss in a child may raise suspicion of atypical forms of RP, which include neuronal ceroid lipofuscinosis and indicate the need for a neurological evaluation, particularly if seizure activity is reported.

### Visual Field Testing

Goldmann perimetry is preferable for initial RP visual field testing out to 90° in the far temporal periphery because the midperipheral retina is involved first in the rod-cone type of disease. The recent introduction of semi-automated kinetic perimetry might prove a valuable alternative. Even moderate stages of rod disease typically show extensive peripheral field loss to the small, I4e Goldmann target, whereas cone-rod disease leaves peripheral fields more intact. Subjects with RP may respond poorly to automated perimeters—careful studies using a Goldmann perimeter are more successful for obtaining representative fields. Macular dysfunction may be well followed by testing the central field by using automated static perimeters (e.g., Humphrey Visual Field Analyzer 24–2 or 10–2 programs). Many patients with RP are unaware of lost peripheral vision or a ring scotoma even after several suggestive events (i.e., recent automobile accidents). The patient will appreciate the physician who simply takes the time to explain visual field test results and may immediately recall instances of previous problems with everyday activities.

### Dark Adaptation Testing

Night vision symptoms occur early in the course of RP disease and must be evaluated by using dark adaptation studies. One of the instruments to do this is the Goldmann-Weekers dark adaptometer. The patient is placed in darkness and asked to detect the dimmest possible (threshold) light, which becomes progressively dimmer as time proceeds. Final absolute threshold sensitivity is normally reached after 30–40 minutes in the dark. An alternative test strategy is to determine only the final thresholds after 45–60 minutes in the dark. Thresholds are tested in several different retinal locations to sample the distribution of disease. Some patients who complain of difficulty seeing at night are found to have normal dark-adapted thresholds. Such patients may have under corrected myopia, and the complaint is really of blurred vision in dimmer light. Other patients may have maculopathy and notice worse acuity in dimmer light, even though normal rod-mediated, absolute dark sensitivity is maintained.

### Color Vision Tests

In degenerative retinopathy, color testing is a useful adjunct to visual acuity tests because it provides additional information about the condition of the

macular cones. Patients with RP rarely volunteer information about problems with color vision because nearly all can readily differentiate the major colors of red, green, and blue. However, in rod-cone dystrophies, tritan (“blue-yellow”) color discrimination loss on the Farnsworth D-15 panel is a sensitive index of early foveal cone involvement and may presage acuity loss within the next few years. In cone dystrophies, loss of color discrimination normally parallels visual acuity loss. The D-15 test, which consists of 15 color chips that must be arranged in color sequence, is simple, is rapid, does not tire the patient, and is easy to score. In the D-15 test, >2 minor neighbor errors indicate pathology. The Farnsworth 100 Hue test is more elaborate but seems to be no more sensitive for detecting maculopathy. The Ishihara and American Optical color plates were designed specifically to identify individuals with congenital red–green abnormality and are less useful than the D-15 test for the evaluation of early macular dysfunction that results from a retinal dystrophy.

### Fluorescein Angiography

Fluorescein angiography (FA) is sometimes used for hereditary maculopathies, such as Stargardt disease and Best disease, or in suspected toxic maculopathy from hydroxychloroquine, chloroquine, or psychotropic agents, but in many cases, the information can be gained from less invasive modalities, such as fundus autofluorescence.

### Fundus Autofluorescence

Fundus autofluorescence with excitation at 488 nm is increasingly recognized to demonstrate characteristic, and in some cases pathognomonic, changes in many retinal diseases especially inherited retinal degenerations.<sup>10</sup> It is thought to elicit the autofluorescence of lipofuscin primarily and, as such, demonstrates distinctive patterns in Stargardt, Best, and bull’s-eye maculopathies. Even in RP, characteristic autofluorescence patterns of a hyperautofluorescence ring have been observed to correlate with retinal sensitivity and optical coherence tomography (OCT) and may reflect progression of RP.<sup>11</sup>

### Optical Coherence Tomography

In vivo high-resolution cross-sectional images of the central retina can be obtained using OCT. In RP, OCT abnormalities range from reduction in retinal thickness caused by photoreceptor loss, to increase in retinal thickness caused by macular edema. Structural changes measured by OCT correlate with functional changes, as measured by visual fields and multifocal ERG, and can also be used to monitor disease progression in RP.<sup>12–14</sup>

### Electro-oculography

Electro-oculography (EOG) result is abnormal whenever the ERG result is abnormal, and thus it provides useful information only when the ERG result is normal. Therefore, EOG is not performed automatically with every ERG examination. One of the very few current uses for EOG is to track the genetic pattern in Best vitelliform macular dystrophy, in which the expressivity is highly variable.

### Multifocal Electoretinography

In contrast to full-field (Ganzfeld) ERG, in which a global response is elicited by stimulation of all the retina by a single light stimulus, in multifocal ERG (mfERG) a localized response is elicited by simultaneous stimulation of multiple discrete areas of the central retina. The local responses may be extracted by correlating the recorded response with the stimulus sequence. In a diffuse retinal disease, such as RP, Ganzfeld ERG is a more useful overall estimator of retinal function. However, mfERG can be used to explore the local aspects of cone function.<sup>15</sup> Diagnostically, it is perhaps most useful in the determination of chloroquine and hydroxychloroquine toxic maculopathies,<sup>16</sup> as well as occult maculopathy and for the differentiation of macular versus optic nerve related central scotomas.

### Visual Evoked Cortical Potential

Visual evoked cortical potential (VECP) monitors visual signals that reach the cortex and is dominated heavily by macular function, with a far smaller contribution from the peripheral retina. Any disturbance of retinal function, altered optic nerve conduction, or visual cortex processing alters the VECP. Retinal, and particularly macular, dystrophies affect the VECP, but these conditions are nearly always identified and monitored better by using other visual function tests.

Retinal function tests have value beyond simple diagnosis because they give insight into the nature of the disease, inform about the severity or stage, and provide information for genetic counseling. Results of the examination must be communicated to the patient because subtyping and

staging the disease provide information about expectations for the course of future vision and the genetic implications for the patient’s family.

### Genetic Testing

As clinical examination and testing lead physicians to a clinical diagnosis, new advances in understanding the genetic basis for disease now support genetic testing to confirm clinical diagnoses and provide additional information about familial risk. In conjunction with genetic counseling, genetic information can be informative for prognosis, as well as providing risk information to family members. From a research perspective, genetic testing improves the understanding of the pathophysiology of the disease and is also a prerequisite before contemplating any gene-based therapies. The speed of identification of genes involved in various retinal degenerations far outpaces the rate of publications produced, and any attempt to enumerate them would be obsolete far before this ever gets to print. The RetNet retinal information network database (<http://www.sph.uth.tmc.edu/Retnet>) provides an updated catalog of genes associated with RP and other inherited retinal diseases. Many of these genes are available for sequencing through commercial enterprises as well as through research institutions. As the number of genes identified as being associated with RP and other retinal degenerations increases, the development of screening systems, such as high-throughput arrays, has made genetic testing feasible in these genetically heterogeneous diseases.<sup>17</sup> Efforts using whole exome sequencing or even whole genome sequencing have also led to the identification of genes involved in retinal degenerations.

The National Eye Institute at the National Institutes of Health is working with the vision community in creating the eyeGENE (National Ophthalmic Disease Genotyping and Phenotyping) Network. This genetic repository allows patients to harness an organization of existing research laboratories within the vision community that have been certified by the Clinical Laboratory Improvement Amendments, and to develop a database of genotypes and phenotypes. The Network will assist in developing public and professional awareness of genotype/phenotype resources that are available to people with various ocular genetic diseases, their clinicians, and scientists studying these diseases. Ultimately, the eyeGENE Network will enhance our understanding of genotype–phenotype correlations and aid in the recruitment of patients interested in participating in future clinical trials related to genetic eye diseases.

## Ocular Findings/Manifestations

### Typical Retinitis Pigmentosa

The key features of typical RP normally found are as follows:

- “Bone-spicule” intraneural retinal pigment.
- Thinning and atrophy of the RPE in the mid- and far-peripheral retina.
- Relative preservation of the RPE in the macula.
- Gliotic “waxy pallor” of the optic nerve head.
- Attenuation of retinal arterioles.

The extent of bone-spicule pigmentation is quite variable—many involved retinas have some, even if very little, of this pigment. This is particularly true in children in whom more subtle abnormalities of RPE pigmentation are more common than are typical spicules. The severity of the features increases with age, such as the amount of pigment, the extent of disc gliosis, and the degree of arteriolar narrowing. Major deviations from this clinical picture suggest atypical RP. In particular, several of the X-chromosome retinal dystrophies (described subsequently) deviate widely from this standard picture. The identification of typical RP is particularly important for clinical trials because diagnosis implies the exclusion of other RP subtypes that may have unusual rates of progression.

Typically, both eyes are affected to a comparable extent,<sup>18</sup> although some degree of difference between each eye is expected normally. Highly asymmetric differences are described as “unilateral retinitis pigmentosa,” in which one eye lags in degeneration by the equivalent of many years, although both eyes invariably show involvement on careful testing.<sup>19</sup> Such apparent unilateral retinitis pigmentosa cases may also result from post infectious causes or blunt trauma to one eye.<sup>20</sup>

Other manifestations of the disease include cataracts, especially of the posterior subcapsular variety, and cystoid macular edema (CME). Both of these complications may reduce the central acuity, even when the underlying disease process affects the peripheral retina only.

Careful clinical examination, careful taking of family history, and diagnostic testing may lead the clinician to suspicion of a certain genetic involvement. Molecular identification of the causative gene is possible in some cases (e.g., pro-23-his rhodopsin mutation) (Fig. 6.14.2). A

**Fig. 6.14.2 “Typical” Retinitis Pigmentosa Changes in a 73-Year-Old Woman Who Had a Pro-23-His Rhodopsin Autosomal Dominant Mutation.** Visible are extensive, intraneural retinal, bone-spicule pigmentation, severely constricted retinal arterioles, waxy pallor of the disc, and extensive retinal pigment epithelium atrophy in the macula and midperiphery (which reveals underlying choroidal vessels). Her visual acuity was 20/50 (6/15), but she made no errors on Ishihara color testing; her fields were severely constricted to 17° tunnel vision with the Goldmann V4e target.

long-sought goal is to correlate a specific gene with a specific phenotype, but this is accomplished rarely because most retinitis pigmentosa mutations result in a similar phenotype. Some unique conditions exist, such as the mutations in RDS/peripherin gene, which may cause a peculiar maculopathy in addition to peripheral retinal degeneration.<sup>21</sup> In general, however, it is not yet possible to predict the specific causative gene from the clinical presentation.

Further, even within the RP cases attributed to a particular gene, such as that which codes for rhodopsin, major variations in the clinical features and disease severity are caused by mutations at different positions within the gene. In rhodopsin RP, the pro-23-his mutation causes fairly typical retinitis pigmentosa<sup>21</sup>; the cys-187-tyr mutation results in a rapid course of degeneration<sup>22</sup>; and the thr-58-arg mutation results in sectoral involvement.<sup>23</sup> The clinical course may vary even within a single family with a single genotype. Consequently, it is impossible to summarize retinitis pigmentosa as a single definition or clinical picture. In general, however, typical RP progresses slowly, such that a period of 1–3 years is needed to document changes.<sup>22</sup>

### X-Linked Retinitis Pigmentosa

X-linked retinitis pigmentosa (XLRP) has features of typical retinitis pigmentosa, although prominent parafoveal atrophy may be present. Affected boys show subtle or modest RPE granularity, but frank, intraneural retinal bone-spicule pigment typically does not appear until the teenage years. Acuity is good during childhood, but by age 20 years, acuity loss and field constriction rule out the acquisition of a driver’s license, and dark-adapted thresholds are elevated by as much as 3 log units (1000-fold sensitivity loss). Night blindness is severe by the mid-teenage years. Rate of vision decline is rapid, and major functional loss is expected by age 30 years; blindness by age 40 years is common.

The clinical features of two different forms of XLRP (RP2 and RP3, the latter caused by mutations in the *RPGR* gene)<sup>24</sup> overlap extensively, and both progress to severe vision disability by young adulthood. All those affected show typical characteristics of RP, although cone vision is affected to a greater degree than in many autosomal forms of RP, particularly in those who have RP3. ERG reveals a major reduction of both the rod and cone responses even in young boys and is essential to stage the disease.

### Leber’s Congenital Amaurosis

The term *Leber’s congenital amaurosis* (LCA) describes a group of retinal dystrophies characterized by very early onset of severe disease. The first sign noticed by the child’s parents is usually nystagmus, a common finding in children who have never developed good central vision. The severity of visual loss can range from moderate to very marked (light perception) and is usually progressive. Children with severe visual loss may self-elicited phosphenes by rubbing their eyes through their eyelids (the oculodigital

**Fig. 6.14.3 Cone Dystrophy in a 37-Year-Old Man.** The bull's-eye maculopathy in this case is not found in all cases of this entity.

sign). Fundus findings are variable. They can be limited to moderate pigmentation abnormalities, but frank atrophic retinal changes are common; marked attenuation of retinal vessel diameter is the norm. The amplitude of all ERG responses is markedly reduced; this test is therefore essential for the differential diagnosis with other ophthalmic diseases associated with congenital visual loss and nystagmus. LCA is usually inherited as an autosomal recessive trait. Mutations of more than a dozen genes can cause LCA; about half of them are also implicated in adult-onset retinitis pigmentosa.<sup>25</sup>

### Cone Dystrophy

Fundus changes are quite variable, with the classic fundus finding being described as a “bull’s-eye” maculopathy (Fig. 6.14.3). Particularly in the early stages, the fundus may appear benign, with minimal diffuse retinopathy and normal vessels and disc. At the other end of the prognosis spectrum are rare patients who develop a central scotoma early in life; the field defect enlarges gradually but relentlessly toward the periphery, with practically total visual loss by late middle age. These patients usually receive the diagnosis of “macular degeneration” in childhood; the condition has been termed “inverse retinitis pigmentosa” because pigment spicules are more abundant in the central retina than in the midperiphery. Typically, ERG findings indicate that cone function (photopic responses) is more affected than rod function (scotopic responses), but both are abnormal.<sup>26</sup> Infrequently, a patient with cone-rod dystrophy has an essentially normal rod but a very reduced cone on ERG and is considered to have “cone dystrophy.”

### Genetics and Pathology

RP can be inherited in an autosomal dominant, autosomal recessive, or X-linked fashion. Frequently, no other family members are known to be affected, a condition known as “sporadic,” “isolated,” or “simplex” RP. According to different surveys, up to 50% of patients with RP are in this category. Many, but not all, of these patients have autosomal recessive RP, and others may be caused by new mutations. Pedigree analysis shows evidence of autosomal dominant inheritance in about 25%, of autosomal recessive inheritance in about 25%, and of X-linked inheritance in about 10% of patients.

RP can be caused by mutations in multiple genes, many of which encode proteins essential for photoreceptor structure and function. To date, the field has identified more than 20 genes which cause autosomal dominant RP, more than 30 genes which cause autosomal recessive RP, and more than 2 genes which cause X-linked RP. More have been located but not identified, and these numbers are expected to increase in the future (Table 6.14.1). The RetNet retinal information network database (<http://www.sph.uth.tmc.edu/Retnet>) provides an updated catalog of genes associated with RP and other inherited retinal diseases.

The identified RP-associated genes may be grouped into mainly five categories:

- Phototransduction.
- Retinal metabolism.
- Tissue development and maintenance.
- Cellular structure.
- Splicing.<sup>27</sup>

Rhodopsin was the first major retinitis pigmentosa gene to be identified.<sup>28</sup> As with rhodopsin, the majority of the RP genes identified thus far involve components of the phototransduction cascade within the rod photoreceptor, which include transducin, phosphodiesterase ( $\alpha$ - and  $\beta$ -subunits of PDE), arrestin, recoverin, and the G protein-coupled Na<sup>+</sup>/K<sup>+</sup> light-activated channel on the rod membrane. Another set of genes code for structural proteins in rod cells and include RDS/peripherin<sup>29</sup> and ROM1.<sup>30</sup> Developmental genes, such as the homeobox gene CRX, are also implicated in the development of cone-rod degeneration.<sup>31</sup> More recently, genes involved in the spliceosomal protein complex, which catalyzes the removal of intronic sequences, such as PRPF3, PRPF8, and PRPF31, have been identified and found to comprise  $\approx 10\%$  of the RP-associated genes.<sup>27</sup>

The molecular mechanisms by which these genetic mutations eventually cause rod-cell death are unclear, although ample evidence indicates that apoptosis is involved in the final pathway of cell death.<sup>32</sup>

That the cone photoreceptors ultimately die from a disease that begins with rod-cell disease remains a puzzle. One hypothesis invokes common elements of the RPE that are involved intimately in the diurnal cycle of phagocytosis of the outer-segment discs shed daily by both rods and cones. In the case of rhodopsin mutation RP, rhodopsin is the major protein in the rod outer segments and the diurnal process of phagocytosis of the shed rod-disc membrane by the RPE may eventually result in secondary RPE pathology. With time, the RPE cannot properly service the cone photoreceptors, which subsequently die as “innocent bystanders.” Alternative explanations are that cone viability depends on the existence of a rod-derived factor<sup>33</sup> and that the mechanical scaffold provided by rods is required for cone survival.

Clinical examination of the retina from a 73-year-old woman who had autosomal dominant RP from a pro-23-his rhodopsin mutation revealed that she had 20/50 (6/15) visual acuity several months before her death, and her fields were only 17°. Her fundus had typical RP changes of heavy bone-spicule pigmentation across the entire 360° periphery, and the underlying RPE was atrophic (see Fig. 6.14.2). After her death, histological examination of her eye showed major loss of the photoreceptors (Fig. 6.14.4). Tissue from the parafoveal region of the left eye in the region of relative preserved retina showed the following:

- Photoreceptor outer segments shortened greatly, such that they are nearly absent, and the inner segments shortened.
- Number of photoreceptor nuclei (outer nuclear layer) decreased greatly, the majority of those left being cone nuclei—virtually no rod photoreceptors remain in this end-stage RP.
- RPE swollen grossly by intraretinal debris, with loss of melanosomes and dispersion of pigment granules.

### Systemic Associations and Differential Diagnosis of Pigmentary Retinopathy

RP is associated with many systemic conditions, of which the following warrant particular attention either because of their incidence (e.g., Usher syndromes, in which early-onset hearing loss is associated with RP) or because the diagnosis, which may be recognized by the ophthalmologist first, has major medical implications. At other times, diagnosis can be important for early treatment with subsequent long-term positive health and vision effects (e.g., Refsum’s disease, abetalipoproteinemia). Secondary causes of RP-like disease should be entertained in the absence of family history of the disease; the differential diagnosis of pigmentary retinopathy includes multiple nonhereditary conditions. Table 6.14.1 lists the main features of many retinal degenerations and associated systemic conditions, with a brief updated list of associated genes as well as acquired conditions that are part of the differential diagnosis.

### Course and Outcomes

Projections about future vision are always difficult in degenerative disease, particularly because the RP subtypes do not have a single clinical course. XLRP typically affects visual acuity by young adulthood, and visual acuity

of some XLRP female carriers also becomes severely impaired. Thus a simple summary of vision loss in the various forms of retinal degeneration is not possible, particularly for visual acuity. In all cases, functional tests using ERG and visual thresholds best establish the current stage of retinal cell function in aggregate and thus provide an initial basis for any prognostic statement. Prognostic statements depend on careful disease subtyping. When subtyping is elusive, analysis of whether the patient has rod-cone disease or cone-rod disease provides vision estimates that may be used for general prognosis.

## “STATIONARY” RETINAL DISORDERS

The generalized main feature of rod-cone or cone-rod degenerations described above, is their progressive nature. In contrast, some inherited retinal disorders are less progressive, and, even though there is often some change over the lifetime, are relatively stable by comparison to most forms of RP.<sup>34</sup> Historically they have carried the descriptor “stationary.”

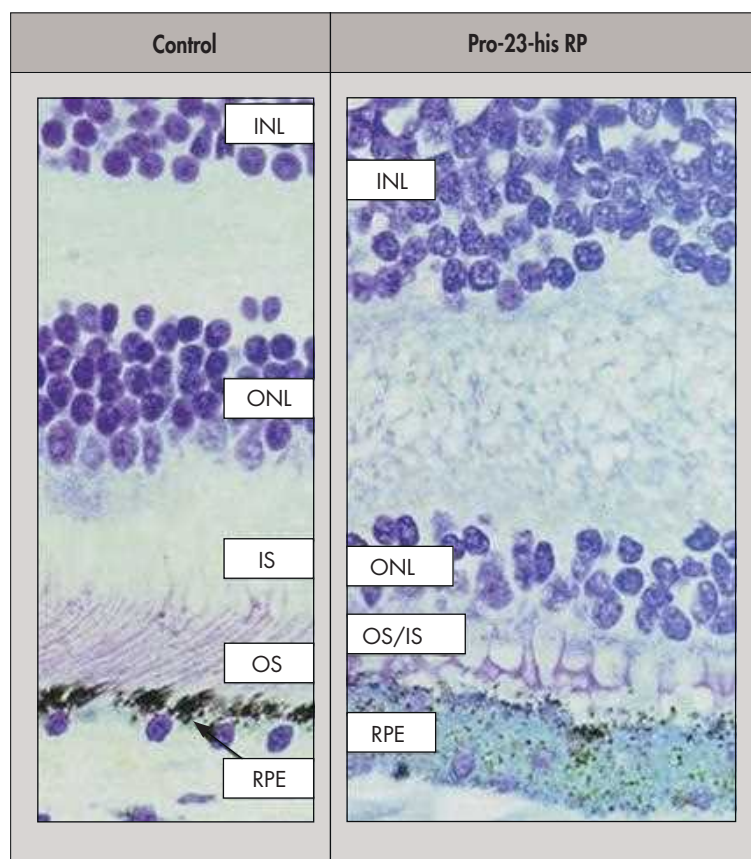

## Congenital Stationary Night Blindness

CSNB comprises a heterogeneous group of disorders that have a common history but differ considerably in terms of clinical pictures and visual

function studies. The main symptom of patients with CSNB is one of night blindness, which is often severe from birth, but color discrimination is unaffected, and visual acuity is usually mildly affected. Refractive changes vary, but high myopia and nystagmus may be present. There are many forms of CSNB that have been classified based on inheritance pattern (all types seen), ERG findings (electronegative most common), and fundus appearance (normal most common).<sup>35</sup> X-linked CSNB is most common and may be confused with XLRP at first presentation, as both occur in young boys and cause complaints of difficult vision at night and show alterations in the fundus pigmentation. Differentiation between these two forms is critical because in CSNB vision remains “stationary” in contrast to the progressive nature of XLRP.<sup>36</sup>

## Congenital Stationary Night Blindness With Normal Fundus

Both ERG and visual field tests are critical in the diagnosis of CSNB. The scotopic ERG is the most significant finding and most commonly demonstrates an electronegative ERG in which the dark-adapted response b-wave amplitude is considerably more reduced than the a-wave amplitude. The photopic ERG is also abnormal with a characteristically wide cone a-wave

**Fig. 6.14.4** Histology of the parafoveal retina of a 73-year-old woman who had a pro-23-his rhodopsin mutation (same patient and eye as in Fig. 6.14.2). Only the macula retained any photoreceptors. The eyes were fixed about 1 hour postmortem. INL, inner nuclear layer; IS, inner segments; ONL, outer nuclear layer; OS, outer segments; RPE, retinal pigment epithelium.

trough. Visual fields are full for CSNB, whereas they are constricted to the Goldmann I4e target even in early XLRP and choroideremia.

A classification of “complete” and “incomplete” CSNB is suggested on the basis of visual function studies performed on patients with autosomal recessive and X-linked recessive CSNB manifesting the most commonly seen Schubert–Bornschein electronegative ERG findings.<sup>37</sup> The complete type of CSNB (also known as type 1, CSNB1) manifests no detectable rod function, with only a slight reduction in cone function in association with diminished vision and myopia. The incomplete type of disease manifests some remaining rod function, more severe cone dysfunction, visual acuity loss, and no specific refractive error. There are now identified genetic bases for these differences.

Mutations in genes involved in the phototransduction cascade (*GNAT1*, *PDE6B*, *RHO*, *RHOK*, and *SAG*) underlie autosomal dominant CSNB. Complete CSNB has been found to be associated with defects in the ON bipolar pathway (*GRM6* and *NYX*).<sup>38</sup> Incomplete CSNB (also known as type 2, CSNB2) is associated with defects in the ON/OFF pathway (*CACNA1F*, *CABP4*, and *CACNA2D4*). Ultimately, it has been found that mutations in *CACNA1F* and *NYX* account for 80% of all mutations in CSNB.<sup>38</sup>

CSNB most often has a normal fundus; however, other less common diseases have an abnormal fundus. A fundus of abnormal appearance in association with CSNB includes Oguchi’s disease and fundus albipunctatus. These two diseases have very little in common, except early-onset non-progressive night blindness.

## Oguchi’s Disease

Named by the Japanese ophthalmologist Oguchi, the characteristic fundus findings in this disease is the yellowish metallic sheen of the posterior pole makes for a clinical diagnosis<sup>39</sup> (Fig. 6.14.5A). After prolonged dark adaptation, the yellowish fundus appearance reverts to normal, a phenomenon described by and named after Mizuo<sup>40</sup> (see Fig. 6.14.5B). Re-exposure to light results in the return of the metallic sheen.

Cone function appears normal. Rod function is abnormal, with normal rod thresholds reached only after 4 hours or longer (30 minutes is normal) and scotopic ERG showing only a small electronegative response, even when the rod thresholds have reached normal values. Oguchi’s disease is

**Fig. 6.14.5** Oguchi’s Disease. (A) The yellowish metallic sheen is apparent nasal to the optic disc. (B) After 3 hours of dark adaptation the fundus reverts to the normal coloration (Mizuo phenomenon).

inherited in an autosomal recessive pattern. Mutations in *RHOK* (rhodopsin kinase) and *SAG* (arrestin), which are involved in terminating the phototransduction cascade, lead to the disease.<sup>39,41,42</sup>

## Fundus Albipunctatus

Like Oguchi’s disease, fundus albipunctatus has a distinctive fundus appearance, which, again, leads to a clinical diagnosis. There are multiple tiny white dots that are very regularly spaced, involve the posterior pole, spare the macula, and extend into the midperiphery (Fig. 6.14.6). Fundus albipunctatus is inherited in an autosomal recessive manner, and the main symptoms are delayed dark adaptation and night blindness. This should be

**Fig. 6.14.6 Fundus Albipunctatus.** Numerous small round yellow-white lesions throughout the retina but excluding the central macula where atrophy and hyperpigmentation is observed.

distinguished from retinitis punctata albescens, which can also have the appearance of a flecked retina but, unlike fundus albipunctatus, behaves clinically like RP. However, although amplitudes of the ERG a-wave and b-wave of the photopic and scotopic responses are diminished under normal test conditions, the scotopic response slowly returns to normal after a few hours in the dark, distinguishing this entity from retinitis punctata albescens. Mutations in retinol dehydrogenase (RDH5) are associated with this disease.<sup>43</sup>

## Congenital Red–Green Color Deficiency

The genes encoding the three main photopigments give rise to the three classes of cone photoreceptors that underlie normal color vision. The genes encoding the red or long-wave-sensitive (L) photopigment and the green or middle-wave-sensitive (M) photopigment are arranged in a head-to-tail tandem array on the X-chromosome (Xq28).<sup>44</sup> Their close proximity and high sequence homology makes this area prone to recombinations during gamete formation in females, giving rise to X-linked color deficiencies. Total “red–green” color vision deficiency caused by lack of red-sensitive cones (protanopia) or green-sensitive cones (deutanopia) affects 2%–3% of men. Partial forms are termed *anomalous color perception* (e.g., protanomaly or deuteranomaly). Tritanopia (total blue blindness) is exceedingly rare. For all forms together, 4%–7% of men manifest some type of congenital color deficiency. Given this frequency, some men who are affected by other retinal degenerations are also “color blind,” and the congenital condition must be differentiated from the acquired disease. Progressive cone dystrophy also impairs color discrimination but is differentiated by abnormal visual acuity and/or peripheral fields, both of which are usually normal in the congenital color deficiencies. Female carriers manifest no clinical signs.

## Blue Cone Monochromatism

Blue cone monochromatism (BCM) is a rare (<1 in 100 000) X-linked disorder. Different mutational pathways have been proposed leading to BCM, both resulting in a loss of functional L- and M-cones, but preserved S-cones and rods.<sup>45</sup> Boys and men affected by BCM have normal nighttime rod vision but poor day vision as a result of the loss of both red- and green-sensitive cone function.<sup>21</sup> Color vision is severely limited, but differences in bluish hues are detectable. Furthermore, BCM causes small-amplitude nystagmus, reduced acuity (between 20/80 [6/24] and 20/200 [6/60]), and glare sensitivity. The fundus may show minimal RPE pigmentary mottling.

All other aspects of vision remain stable in BCM, and acuity may even improve slightly and reach 20/70 by age 20 years, by which time the nystagmus is barely detectable. Some older men with BCM have progressive macular atrophy. The dark-adapted ERG b-wave amplitude is normal or slightly subnormal for patients with BCM, but rod psychophysical threshold sensitivity remains normal, which differentiates BCM from degenerative rod disease cases. The light-adapted cone ERG single-flash and flicker responses are reduced by >80%–95%. Only 1% of cones are blue-sensitive cones, and no blue-sensitive cones are found within the human fovea, which accounts for the poor acuity in patients with CM. Female carriers show no changes. An X-linked family history helps differentiate BCM from autosomal dominant or autosomal recessive, early age, progressive cone dystrophy.

## Achromatopsia

Achromatopsia, or “total color blindness,” is monogenic congenital retinal dystrophy that causes reduced visual acuity, extremely limited color vision discrimination, nystagmus, and photophobia. It is inherited as an autosomal recessive trait, and thus both sexes are affected.

Patients with BCM as well as those with achromatopsia fail the Ishihara and American Optical Hardy-Rand-Rittler color plate tests and the Farnsworth D-15 and 100 Hue tests. Differentiation between those with achromatopsia and patients with BCM is aided by specially designed “blue arrow” color plate tests, which boys and men affected by BCM pass but those with achromatopsia fail.<sup>46</sup> Achromatopsia was traditionally regarded as a “stationary” disease, but more recent evidence points to slow progression over time.<sup>47</sup>

## Ocular Albinism

Ocular albinism occurs in several forms and follows all the inheritance patterns. When restricted to the eyes (“ocular albinism” [OA]) is inherited most frequently as an X-linked recessive trait. When the skin is also involved (“oculocutaneous albinism” [OCA]) inheritance is usually autosomal recessive. All forms are evident from birth and cause moderate-amplitude nystagmus, which the parents notice quite early. The fundus is hypopigmented, and the iris may transilluminate. Acuity is between 20/70 and 20/200 but is difficult to test precisely during infancy. Color vision remains normal, and nyctalopia does not occur. The foveal reflex may be muted, and the fovea may be hypoplastic. The ERG result is normal or even supranormal because of enhanced intraocular light reflection. OCA results with systemic manifestations include Hermansky–Pudlak syndrome (platelet dysfunction) and Chediak–Higashi syndrome (white blood cell lysosomal dysfunction). Diagnosis is made through clinical examination. Vision remains stable. Confusion arises in the differentiation of ocular albinism from the “blond fundus” of patients who have pale skin and hair tones but normal acuity. The pattern-onset visual evoked potential is useful for this differential diagnosis.<sup>48</sup>

## FEMALE CARRIERS OF X-LINKED RETINAL DEGENERATIONS

Female carriers of X-chromosomal retinal dystrophies may manifest retinal pigmentary changes and have functional vision impairment that present special difficulty in diagnosis. Recognition of the carrier state is important to establish the correct inheritance pattern for family genetic counseling. Some carriers have a severe vision abnormality, which may lead to a misdiagnosis of autosomal dominant disease. In female carriers, one of the two X chromosomes has a mutant gene. As a result of random X-chromosome inactivation, only one gene is active in each cell (the Lyon hypothesis). Because the mutant gene is retained in some retinal cells during early development, clusters of neighboring cells have the disease, and there are patches of clinical disease that mimic a mild form of the fully expressed male condition in choroideremia, XLRP, and X-linked ocular albinism. Carriers of juvenile retinoschisis, blue cone monochromatism, CSNB, and color vision dichromatism show no fundus changes and no functional vision abnormality. Carriers of autosomal recessive disease rarely show retinal changes or have visual symptoms.

Female carriers of XLRP (Fig. 6.14.7) show one or more small or large retinal patches of typical, intraneural retinal bone-spicule pigmentation and atrophy of the underlying RPE and choriocapillaris in >50% of cases. Many carriers have myopic astigmatism at an oblique axis. Although vision is involved minimally in the majority, some are functionally blind by late

**Fig. 6.14.7** X-linked female retinitis pigmentosa carrier affected by lacunae of disease. Atrophy of retinal pigment epithelium and intraneural retinal bone-spicule pigment result. Acuity is 20/200 (6/60) because of macular atrophy.

**Fig. 6.14.8** Punctate granularity and attenuation of the normally uniform pigmentation of the retinal pigment epithelium in a female carrier of X-linked ocular albinism. This can often be associated with iris transillumination defects.

middle age or older age. Changes progress with time but generally do so much more slowly than those in XLRP-affected men. An ERG is very helpful, as amplitudes of one or more ERG components are reduced in 80%–95% of XLRP carriers.<sup>49</sup> Furthermore, the ERG amplitudes generally correlate with the expected severity of overall vision loss in later years.

Female carriers of choroideremia also show widespread retinal pigmentary disturbance of the RPE in the periphery and into the macula in 90% of cases. However, very few carriers have any visual symptoms beyond mild glare sensitivity in later age, and visual acuity remains normal. ERG results are affected far less frequently than those of XLRP carriers; fundus examination is the most sensitive means of detection. Most carriers of choroideremia have emmetropia or hyperopia, in contrast to the myopia that is typical of carriers of XLRP. Progression has been observed in some carriers of choroideremia.<sup>49,50</sup> Female carriers of X-linked ocular albinism (Fig. 6.14.8) show punctate RPE pigmentation across the entire fundus and RPE thinning in the periphery (a mild version of changes found in the affected men), which may mimic the “salt and pepper” appearance of congenital rubella retinopathy. Visual acuity is not affected, and the ERG result is normal. Symptoms do not extend beyond mild glare sensitivity to bright light. Carriers of non-X-linked albinism rarely show fundus changes.

## TREATMENT OF RETINAL DEGENERATIONS

No treatment currently has been approved by the U.S. Food and Drug Administration (FDA) for retinal degenerations. Treatment trials to date have spanned vitamin supplementation, medical therapy, gene

**Fig. 6.14.9** Hydroxychloroquine Bull's-Eye Parafoveal Atrophy. This clinical sign is often a late indicator of retinal toxicity. Other testing, such as Humphrey visual field testing and OCT especially, can detect signs of toxicity prior to any clinically observable retinal abnormalities.

**Fig. 6.14.10** Clinical Appearance of Retina in a Patient With Bardet-Biedl Syndrome. Retina demonstrates extensive peripheral retinal pigment epithelium thinning and parafoveal retinal pigment epithelium atrophy.

transfer-based therapy, stem cell-based therapy, and retinal implantation, with many of them currently utilized in practice and many more likely to start in the next few years.

## Vitamin A

A long-term study of oral vitamin A palmitate supplementation (15 000 IU daily) administered to 600 patients who had typical RP showed a modest but positive slowing of vision loss.<sup>51</sup> In all cases in aggregate, vision loss declined to 8.3% per year compared with 10% per year in controls. Such slight slowing of degeneration is rarely noticeable to an individual patient over a short period, but it may provide additional years of vision when spread over a lifetime. The rescue mechanism is unknown, but vitamin A is essential for the formation of light-sensitive rhodopsin. Opsin alone, in the absence of vitamin A, may exhibit a small degree of toxicity and possibly cause photoreceptor demise over a lifetime. In the same study,<sup>51</sup> the administration of vitamin E (400 IU daily) without vitamin A hastened the degeneration by a small but statistically significant amount. However, when combined with vitamin A, low doses of vitamin E did not substantially alter the slowing of progression afforded by vitamin A palmitate alone, and thus the modest amount of vitamin E in multivitamin formulations may not be detrimental when taken along with vitamin A.

If this treatment is suggested, the patient is advised to use vitamin A for the long term and to expect no immediate benefit in vision. Yearly checks of serum liver enzymes and/or vitamin A levels are advisable while vitamin A is taken at high dosage, and discontinuation is necessary if pregnancy is expected. The main caution is to the female patient who must be counseled on the risk of teratogenicity of high doses of vitamin A, and as such, it should not be recommended for women who are pregnant or planning to become pregnant.<sup>52</sup>

## Docosahexaenoic Acid

Docosahexaenoic acid (DHA), a 22:6 fatty acid, is the major lipid component of rod photoreceptor membranes and is important for the maintenance of membrane fluidity required for rods to function. Abnormal cholesterol and serum lipid levels have been reported in some patients with RP,<sup>53</sup> and DHA levels are particularly and somewhat consistently low in patients with XLRP.<sup>54</sup> On the basis that insufficient DHA may affect photoreceptor survival, two randomized clinical trials designed to determine whether DHA dietary supplementation slows progression in retinal degeneration have been completed. The first one included only male patients with X-linked retinitis pigmentosa,<sup>55</sup> and the second one recruited patients regardless of inheritance mode.<sup>56</sup> Unfortunately, these studies did not show a statistically significant effect of DHA on the course of visual loss. A recent study did report that a diet high in long-chain omega-3 fatty acids could slow the rate of visual acuity of patients with RP who were taking vitamin A.<sup>57</sup> Lutein has also been investigated as a potential therapy for RP in addition to vitamin A, with some reported positive effects.<sup>58</sup>

## Carbonic Anhydrase Inhibitors for Cystoid Macular Edema

Some patients with RP have CME, possibly because the efficiency with which fluid is pumped across the RPE is compromised or because of slow retinal vascular leakage. Some studies show that treatment with acetazolamide may be of benefit,<sup>59</sup> with an initial dose of 250 mg daily, increased to 500 mg daily if no effect is apparent. A trial of several weeks is warranted, with successful outcome judged by improved visual acuity on careful repeated measurements or by decreased CME on FA or OCT. If decreased CME is observed by FA after several weeks of use, the continuation of acetazolamide may be considered even if visual acuity has not improved, provided the patient is able to tolerate the drug. Topical carbonic anhydrase inhibitors, such as dorzolamide, have also been used in this setting.

## Gene Therapy

Because RP arises as a consequence of mutations in many genes, one rational approach to therapy relies on correcting the genetic defect. Gene therapy can be broadly divided into three main approaches: (1) delivering a normal copy of the specific affected gene to the retina with a virus vector or other delivery method, (2) inactivating a mutating gene whose gene product has a deleterious effect, and (3) introducing a new gene into a tissue to help fight disease. An example is gene replacement therapy as treatment for autosomal recessive LCA from mutations in the *RPE65* gene. After successful gene therapy in an *RPE65* dog LCA model,<sup>60</sup> this was extended to a human *RPE65* trial, with preliminary evidence of benefit to visual function.<sup>61–63</sup> More long-term study of participants in this study indicate that the effects of treatment are long lasting.<sup>64</sup> Currently, clinical trials involving gene therapy for a number of retinal degenerations, including Stargardt, choroideremia, X-linked retinoschisis, achromatopsia, and *MYO7A* Usher syndrome are currently underway (<http://www.clinicaltrials.gov>).

## Neurotrophic Factors

A report in 1990 showed that intraocular injection of basic fibroblast growth factor effectively slowed photoreceptor degeneration in the RCS rat model of retinal degeneration.<sup>65</sup> These and other results implied that effective therapies may be developed to slow the rate of degeneration radically in these diseases.<sup>66</sup> Ciliary neurotrophic factor (CNTF), delivered intravitreally, has been effective to rescue photoreceptors in multiple animal models of retinal degeneration.<sup>67,68</sup> Small clinical trials in humans have now been done with CNTF delivered by encapsulated cell technology in patients with advanced RP<sup>69,70</sup> and in patients with age-related macular degeneration (AMD) with geographical atrophy.<sup>71</sup> In these small studies, the implants were well tolerated and each reported some positive effects. Long-term follow-up of a cohort of patients with retinitis pigmentosa failed

to show evidence of efficacy in acuity, field sensitivity, or retinal structural measures.<sup>72</sup> Studies using CNTF in the treatment of retinal degenerations are currently underway (<http://www.clinicaltrials.gov>).

## Stem Cell–Based Therapies

The previously mentioned therapies address the function and longevity of existing retinal cells. However, as the name implies, patients with retinal degenerations lose certain cells with time. The two main approaches involving stem cells involve either a regenerative approach, which involves the generation of more differentiated cells to replace a specific cell type that has been lost, or another approach to harness the trophic factors generated by relatively undifferentiated stem cells to provide the molecular boost to fortify existing cells (similar to the previous section). Recently, a recent report on the short-term use of transplanted human-derived RPE cells demonstrated short-term safety.<sup>73</sup> Research is progressing quickly in this area, and future studies are being planned.

## Retinal Prostheses/Implants

Another method to address the loss of retinal cells seen in a range of retinal degenerations has been to use an artificial implant that would detect light, convert light energy into an electrical signal, and then pass on that electrical signal to other cells in the visual system that would get the electrical signal to the brain, where it could be interpreted as vision.<sup>74</sup> Several commercial implant prototypes employing slightly different approaches, with some implants residing in an epiretinal position and others subretinally or suprachoroidal locations, are currently being studied in clinical trials in Europe, Australia, and the United States. Most make use of an external video processing unit, but one device, the Alpha IMS approach, utilizes internal light-sensitive photodiodes and is approved in Europe. A video illustrating the surgical approach as well as patients' perspectives from the Alpha IMS retinal prosthesis can be found on <http://rsnpb.royalsocietypublishing.org/content/280/1757/20130077.figures-only>. Another retinal prosthesis, the Argus II, which utilizes an external video camera and processing unit, is the only retinal prosthesis currently FDA approved for use in the United States, and 5-year data results are available.<sup>75</sup> The concept has been around longer than that of stem cell–based therapies, and several clinical trials using various versions of these implants have been conducted. Progress continues to be made, especially as technology evolves.

Macular Dystrophies

David G. Telander, Kent W. Small

6.15

**Definition:** The process of premature retinal cell aging and cell death, generally confined to the macula, in which no clear demonstrable extrinsic cause is evident, and a genetically determined defect is confirmed or implicated.

Key Features

- Common to have yellowish material within or beneath the retinal pigment epithelium.
- Loss of macular photoreceptors and retinal pigment epithelial cells causing macular atrophy.
- Loss of central vision.

Associated Features

- Neural retinal, retinal pigment epithelial, and choroidal atrophy commonly limited to the macula.
- Bullseye appearance for some macular dystrophies.
- Pigment clumps in the posterior pole, midperiphery, or far periphery seen rarely.
- Optic atrophy, retinal vascular attenuation, macular edema, and choroidal neovascularization seen rarely.

INTRODUCTION

The macula is the center of all human vision and is critically unique to our visual function. Its irreducibly complex design requires many unique proteins that allow light to be converted to neuronal impulses (phototransduction). Macular dystrophies are rare genetic disorders that can cause severe central vision loss for the individuals affected. Understanding the genetic causes of these dystrophies allow us to see the various types of clinical abnormalities that arise from specific gene defects in a complex system involved in macular function. Molecular genetics has been instrumental in unlocking the secrets of these mechanisms and has given us a better understanding of the macula. The first retinal degeneration mapped by genetic linkage was one type of X-linked retinitis pigmentosa (XLRP) in 1984. Subsequently, linkage of autosomal dominant retinitis pigmentosa (ADRP) to chromosome 3 was achieved by McWilliams et al.<sup>1</sup> The first macular dystrophy to be mapped was North Carolina macular dystrophy in 1992 by Small and colleagues.<sup>2</sup> Since then there have been many important contributions by numerous groups around the world. There are many online resources to catalog these conditions, including Online

Mendelian Inheritance of Man (OMIM, <http://www.ncbi.nlm.nih.gov/omim>), RetNet (<https://sph.uth.edu/Retnet/>), and Retina International (<http://www.retina-international.org/>).

From a clinical perspective, significant phenotypic variations even within a single family are common, making it imperative to examine as many other family members as possible. For example, differences in phenotypes can represent mutations in different genes, different mutations in the same gene, and/or variability in the genetic background in which a single gene/mutation is expressed. In general most macular dystrophies are autosomal dominant and the appearances of the macular abnormality are severe, but the visual acuity is better than one would expect. The autosomal recessive macular dystrophies tend to have worse visual acuities than one would expect from examination.

In contrast to age-related macular degeneration (AMD), which is a multifactorial and multigenic disease, macular dystrophies are usually thought to be caused primarily by a disruption of a single retinal gene. Table 6.15.1 demonstrates how identification of genetic phenotypes has given us insights into macular dystrophies. Table 6.15.2 categorizes the macular dystrophies by the location of the affected cell/gene.

The purpose of this chapter is to highlight the clinical features of some of these macular dystrophies, discuss the pertinent molecular genetics and pathophysiology of these diseases, and correlate the functional consequences of the mutant gene products in the framework of the known anatomy and physiology of the retina and retinal pigment epithelium (RPE). Obviously, every disease cannot be reviewed. However, the intention is to convey certain underlying biological principles that can be extended to understand the molecular pathogenesis of other disease processes.

With the advent of gene therapy, stem cell therapy, artificial vision, and a plethora of new retinal pharmacologicals, proven therapy for these disorders is in the near future. In addition, therapies to halt the progression of choroidal neovascularization have progressed and can benefit some who develop this complication.

STARGARDT DISEASE AND FUNDUS FLAVIMACULATUS

EPIDEMIOLOGY AND PATHOGENESIS

Stargardt disease is the most common macular dystrophy, with an estimated incidence of 1:8000–10 000. Stargardt disease is also known as Stargardt macular dystrophy. It usually presents within the first two decades, but the central vision loss may not occur until later in life.<sup>3</sup>

Stargardt disease (STGD1) most commonly is inherited in an autosomal recessive manner caused by various sequence mutations in adenosine

TABLE 6.15.1 Examples of Cellular Specificity of Macular Dystrophy Genes

Cellular Location	Retinal Dystrophy	Chromosome	Gene
RPE specific	AD Best	11q12.3	VMD2, bestrophin (chloride channel)
	AD Sorsby's macular dystrophy	22q12.3	TIMP3 (tissue inhibitor of metalloproteinase)
	Malattia leventinese (Doyle's honeycomb macular dystrophy)	2p16	EFEMP1 (EGF-containing fibrillin-like extracellular matrix protein 1)
Rod specific	AD Stargardt macular dystrophy	6q14	ELOVL4 (photoreceptor-specific elongation of very long chain fatty acids)
Cone specific	AD cone dystrophy	6p21.1	GUCA1A (guanylate cyclase activator 1A)
Cone-rod specific	AR Stargardt	1p22.1	ABC4 (ATP binding cassette protein found in rods and foveal cones)
	AD adult foveal macular dystrophy	6p21.2	RDS/peripherin (cone and rod outer segment glycoprotein in disc membranes for structural integrity)

AD, Autosomal dominant; AR, autosomal recessive; ATP, adenosine triphosphate; EGF, endothelial growth factor; RPE, retinal pigment epithelium.

TABLE 6.15.2 Macular Dystrophies and Example Genes

Disease Name	Gene	Chromosome	Inheritance
Best 1	VMD2 /TU15B	11	AD
Best 2	VMD2L1	19	
	VMD2L2	1

Glomerulonephritis type II and drusen			

AD, Autosomal dominant; AR, autosomal recessive.

triphosphate-binding cassette (*ABCA4*) gene, which has been localized to chromosome 1p21–22.<sup>4–7</sup> *ABCA4* is a very large gene with more than 900 identified disease-causing mutations.<sup>3</sup> While 60%–70% of these patients have a detectable mutation in the *ABCA4* gene, the carrier state is thought to be as frequent as 1:20 people.<sup>3</sup> *ABCA4* normally encodes for a protein involved in the visual cycle. Lipofuscin buildup in the subretinal space appears to be related to a mutation in *ABCA4* and the resulting production of a dysfunctional protein. Lipofuscin is a complex mixture of bisretinoid fluorophores amassed by RPE cells. In the RPE, lipofuscin does not form as a result of oxidative stress, unlike in other cell types. Instead it forms because of a nonenzymatic reaction of vitamin A aldehyde in photoreceptor cells that is transferred to the RPE by the phagocytosis of the photoreceptor outer segments. In recessive Stargardt (STGD1) and *ELOVL4*-related retinal dystrophies (STGD3), the formation of lipofuscin is accelerated, leading to cell death.<sup>8</sup> Carrier parents are unaffected. Interestingly, mutations in this gene can also lead to other retinal diseases such as AMD, retinitis pigmentosa (RP), and autosomal recessive cone–rod dystrophy.<sup>3,8,9</sup> These *ABCA4*-related dystrophies likely represent a spectrum of phenotypes with overlapping retinal changes, just as Stargardt disease itself exhibits great variability in clinical expression.<sup>10–12</sup>

In addition to recessive Stargardt disease, there are other rarer forms inherited as dominant rather than recessive traits. Autosomal dominant Stargardt (STGD3) is a rarer form of this condition and is caused by mutations of the *ELOVL4* gene, which codes for a photoreceptor-specific membrane-bound protein that plays a role in long chain fatty acid biosynthesis.<sup>13</sup> Several other retinal diseases have been mapped near to *ELOVL4*, including retinitis pigmentosa, Leber’s congenital amaurosis, cone–rod dystrophy, North Carolina macular dystrophy, early onset dominant drusen, and progressive bifocal chorioretinal atrophy.<sup>14–16</sup>

OCULAR MANIFESTATIONS AND DIAGNOSIS

The phenotypic variation of mutations in the *ABCA4* gene presents in many forms as described earlier.

Stargardt disease classically is marked by the accumulation of discrete “pisciform” flecks at the level of the RPE (Fig. 6.15.1).<sup>17,18</sup> Early in the disease, patients may have few flecks, but they often will develop more macular flecks along with patches of characteristic central atrophy. Fundus flavimaculatus patients have mutations in the same gene but present with pisciform flecks in the peripheral macula and retina sparing the fovea. Therefore, early in the disease, fundus flavimaculatus patients tend to retain their central vision, but later in life they usually develop central macular atrophy, central vision loss, color vision loss, and photophobia. Stargardt patients, on the other hand, develop a macula with a “beaten bronze” appearance caused by atrophic changes in the RPE. In addition, they also often have a “dark” or “silent” choroid on fluorescein angiography that appears as a prominent retinal circulation against hypofluorescent choroid. Although this finding can be helpful in making the diagnosis.

Fig. 6.15.1 Stargardt Disease.

only up to one-fourth of patients have a dark choroid.<sup>19</sup> On angiography the pisciform flecks do not stain. Autofluorescence can be helpful in showing the lipofuscin in flecks and atrophic areas, which will show photoreceptor dysfunction<sup>20</sup> (Fig. 6.15.2). The electroretinogram (ERG) is normal early in the disease but may be reduced in more advanced cases. Of note, the ERG findings do not directly correlate with clinical findings.<sup>21</sup> High-resolution optical coherence tomography (OCT) can show atrophic changes in the photoreceptors and RPE, and lipofuscin deposits can be detected within the parafoveal RPE<sup>22–24</sup> (Fig. 6.15.3). Interestingly, these changes usually precede the occurrence of fundus abnormalities. The OCT can also help with diagnosis and aid in determining the status of the photoreceptor layer in the macula, which is beneficial in the assessment of central vision.<sup>23</sup>

PATHOLOGY

Histological studies reveal that Stargardt patients have a buildup of a lipofuscin-like pigment in the RPE.<sup>25</sup> The mouse model (a knockout *abcr*–/–) of Stargardt disease also has an accumulation of lipofuscin in the RPE. Specifically, the toxic *bisretinoid*, *N-retinylidene-N* retinylethanolamine (A2E) protein builds up, suggesting its role in causing the disease.<sup>4</sup>

TREATMENT, COURSE, AND OUTCOME

To date there is no known proven treatment for this disease. As *ABCA4* plays a role in vitamin A processing in the visual cycle, additional vitamin A is suspected to make the disease worse. Therefore all forms of vitamin A supplements are discouraged for these patients.<sup>26</sup> Polyunsaturated fatty acids such as docosahexaenoic acid (DHA) have been shown to reduce toxicity of A2E and are therefore recommended especially for patients if they are autosomal dominant Stargardt.<sup>27</sup>

Gene therapy has been initiated for Stargardt, specifically a 48-week phase 1/IIa dose escalation study is currently investigating SAR422459 (a lentiviral vector gene therapy carrying the *ABCA4* gene) for the treatment of Stargardt. Eligible patients must have two pathogenic *ABCA4* gene variants confirmed by segregation analysis of parental samples. (<http://clinicaltrials.gov/ct2/show/NCT01367444>). Another clinical trial has been launched using RPE precursor cells derived from embryonic stem cells injected subretinally for patients with Stargardt disease. Retinal pigment epithelial cells derived from human embryonic stem cells (hESC\_RPE) are surgically implanted in the submacular space.<sup>28</sup> Saffron, ALK-001 (C20-D3-retinyl acetate), MP-4, and DHA are all being studied in additional clinical trials for Stargardt disease (see <https://clinicaltrials.gov/>).<sup>3</sup>

Individual members of families with Stargardt disease often display tremendous variability in presentation, course, and outcome. The visual prognosis ranges from 20/5 to 20/200 as determined by the extent of macular atrophy depending mostly on the extent of macular atrophy for both Stargardt and fundus flavimaculatus.<sup>18,19,29</sup> Choroidal neovascularization is rare but can worsen the prognosis if it occurs.<sup>30</sup>

## VITELLIFORM MACULAR DYSTROPHY (BEST DISEASE)

### EPIDEMIOLOGY AND PATHOGENESIS

Vitelliform macular dystrophy is an inherited macular dystrophy in which lipofuscin accumulates in the central macula, causing progressive central vision loss. Vitelliform dystrophy can present early in life (described as Best disease), but the onset of symptoms can vary widely. The adult-onset form of vitelliform dystrophy (described later) usually presents in middle age. Best disease is an autosomal dominant macular dystrophy linked to mutations in the bestrophin (*VMD2*) gene. Like Stargardt, Best patients can be highly variable in clinical phenotype, but is quite rare compared to Stargardt disease. *VMD2* encodes for a transmembrane protein, which acts as an ion exchanger.<sup>31–33</sup> *VMD2* is expressed in the RPE cell membrane and appears to be important in the formation of chloride channels.<sup>34</sup> This leads to the accumulation of lipofuscin through mechanisms that are still unclear. Several mutations within the bestrophin gene have been identified and are associated with both classic Best and adult vitelliform-like presentation.<sup>35</sup> Interestingly, some patients with the mutation can be completely free from any clinically observable retinal changes. Incomplete penetrance by clinical exam alone has been well documented, although electro-oculogram (EOG) generally does demonstrate abnormalities.<sup>36</sup> In fact, Best disease expresses a great deal of phenotypic variability even within a single family.

### OCULAR MANIFESTATIONS AND DIAGNOSIS

Vitelliform dystrophies are characterized by bilateral yellow, yolk-like (vitelliform) macular lesions (Fig. 6.15.4). Although Best disease presents during childhood, adult vitelliform typically presents later in life. In Best, the diameter of the lesion is in the range of 1–5 mm. For Best patients, the lesion will change later in life resulting in macular scarring and atrophy. This may make it more difficult to diagnose later.

**Fig. 6.15.4 Best Disease.** Typical vitelliform lesion from an 11-year-old girl. (Courtesy Ola Sandgren, University Hospital of Umeå, Sweden.)

The stages or evolution of the macular lesions are described as progressing from (1) previtelliform stage to (2) vitelliform stage to the (3) scrambled egg stage with or without hypopyon finally to (4) the atrophic stage. Rarely, the lesions may be multifocal.<sup>37</sup> All Best patients have a light-to-dark (or Arden) ratio of less than 1.5 and often close to 1.1 when tested with the EOG. ERG testing shows only occasionally a reduced C-wave. Therefore

this is the only disease with relatively normal ERG results associated with an abnormal EOG. Moreover, OCT findings appear to be very specific (Fig. 6.15.5). In Best disease, the OCT reveals that the vitelliform material appears as a dome-shaped, hyperreflective, and homogenous lesion (see Fig. 6.15.5) located below the hyperreflective photoreceptor layer.<sup>38</sup>

## **PATHOLOGY**

Best patients have an accumulation of lipofuscin-like material throughout the RPE.<sup>39–42</sup> Unlike with Stargardt disease, despite the accumulation of lipofuscin-like material in the RPE, these patients do not exhibit a dark choroid effect on fluorescein angiography. In addition, Best patients can lose vision from atrophy and scarring in the macula, not from accumulated material in the RPE.

## **TREATMENT, COURSE, AND OUTCOME**

Even though the age of onset of Best disease is variable, most patients present in childhood. Best patients usually have good visual acuity when

the “yolk” remains intact, but the vision drops when macular atrophy begins.<sup>37</sup> Visual acuity can decrease to the 20/200 range, but most patients will keep enough vision in at least one eye to read and drive. Rarely, Best patients develop choroidal neovascular membranes (CNVs).<sup>37</sup>

## **ADULT VITELLIFORM MACULAR DYSTROPHY/ ADULT-ONSET FOVEOMACULAR DYSTROPHY (PATTERN DYSTROPHY)**

### **EPIDEMIOLOGY AND PATHOGENESIS**

Unlike Best disease, the adult-onset form of vitelliform dystrophy usually presents in middle age and typically only causes mild, if any, central vision loss. While these two diseases can be phenotypically similar, the clinical course is highly divergent. While Best is caused by mutations in *VMD2*, adult vitelliform dystrophy has been associated with mutations of both *VMD2* and retinal degeneration slow (*RDS*, *PRPH2*), but the causative

**Fig. 6.15.5** An 80-Year-Old Patient With Best Disease in the Vitelliruptive Stage (Right Eye) and Atrophic Stage (Left Eye). Fundus photos (A), red free (B), fluorescein angiogram (C), optical coherence tomography (D), and histology (E). Note optical coherence tomography findings show characteristic hyporeflective subretinal zone consistent with subretinal deposit at this stage.

**Fig. 6.15.7 Adult Vitelliform Macular Dystrophy.** Color photograph shows the vitelliform deposit in the macula settled inferiorly, and fundus autofluorescence. (Courtesy Jay S. Duker.)

gene cannot be found in most patients with adult vitelliform dystrophy.<sup>31,43</sup> Interestingly, several mutations within the bestrophin gene have been identified and are associated with both classic Best and adult vitelliform-like presentation.<sup>35</sup> RDS encodes a protein called peripherin. This protein is essential for the normal function of light-sensing (photoreceptor) cells in the retina. How a mutation in RDS only affects the macula and not the remainder of the retina is unclear.

## OCULAR MANIFESTATIONS AND DIAGNOSIS

Adult vitelliform (Figs. 6.15.6) and Best disease can often appear very similar. While Best presents during childhood, adult vitelliform typically presents later in life. In Best the diameter of the lesion is in the range of 1–5 mm, whereas in adult vitelliform the lesion tends to be smaller (Fig. 6.15.7). Adult vitelliform degenerations include foveomacular dystrophy of

**Fig. 6.15.8 Optical Coherence Tomography Shows the Typical Vitelliform Deposit in the Subretinal Space.** (Courtesy Jay S. Duker.)

Gass, and coalescent, widespread, cuticular drusen that form vitelliform lesions in the macula.<sup>44</sup> Adult vitelliform can be differentiated from Best disease by having a near normal EOG (Arden ratio <1.7), but the multifocal ERG may be reduced. Also the OCT will show the absence of subretinal fluid in adult vitelliform dystrophy (Fig. 6.15.8) but not Best disease.<sup>45</sup>

## PATHOLOGY

Adult vitelliform dystrophy patients have damage at the level of the RPE with focal loss of the photoreceptors in the areas of atrophic RPE cells in the fovea. Pigmented material is found between the retina and Bruch's membrane. OCT images localize the vitelliform lesion to the highly reflective photoreceptor-RPE complex.<sup>22</sup> Interestingly, Gass found no abnormal accumulation of lipofuscin in RPE cells in these patients.<sup>44</sup> Other investigators have found high concentrations of lipofuscin in RPE cells and suggest that this accumulation is responsible for the foveal lesion.<sup>40</sup> Moreover, autofluorescence studies support this hypothesis.<sup>46</sup>

## TREATMENT, COURSE, AND OUTCOME

Adult vitelliform dystrophy usually presents during the fourth to sixth decade, and visual symptoms are usually metamorphopsia and mildly blurred vision. Rarely, these patients can also develop CNVs.<sup>47</sup> Interestingly, as in Best disease, adult vitelliform dystrophy patients usually only lose significant vision when atrophy and scarring occur. Best disease should be distinguished from adult vitelliform dystrophy, as there are potential genetic implications that require appropriate counseling.<sup>48</sup>

## DOMINANT DRUSEN (DOYNE'S DRUSEN, MALATTIA LEVENTINESE)

## EPIDEMIOLOGY AND PATHOGENESIS

Familial (dominant) drusen is a rare autosomal dominant disease with variable expressivity and age-dependent penetrance.<sup>49</sup> All are due to a single mutation from an arginine to a tryptophan at amino acid 345 in the *EFEMP1* gene.<sup>50</sup> While initially all patients with the R345W mutation had identical haplotypes suggesting a common founder, there were recently reported two separate Japanese and Indian families also with the R345W mutation but with unique haplotypes. This suggests that the same mutation had spontaneously arisen in three different ethnicities.<sup>51,52</sup> The mutant *EFEMP1* is misfolded and secreted inefficiently, thus accumulating within the RPE and causing drusen.<sup>30,53</sup> Another locus on chromosome 6q14 adjacent to the North Carolina dystrophy gene (*MCDRI*) has been identified, also, in those with dominant drusen.<sup>54–56</sup> However, these cases are more consistent with North Carolina macular dystrophy with only drusen present and were misdiagnosed as dominant drusen.

This disease is thought to arise from an inborn error of metabolism localized to the RPE. One hypothesis is that the defect is in an intercellular matrix protein or a structural protein, which leads to the development of abnormal basement membranes.

## OCULAR MANIFESTATIONS AND DIAGNOSIS

Typically, diffuse drusen extend outside the macula and involve retina nasal to the optic disc.<sup>57</sup> The drusen, themselves, may be large and sparse or form a constellation of tiny dots, called *cuticular* or *basal laminar drusen*. Sometimes, basal laminar drusen coalesce to form a vitelliform lesion.<sup>58</sup> The drusen usually first appear around the third or fourth decade of life and become quite numerous by middle age. In the late stages, pigmentations occur, along with atrophy of the RPE, choriocapillaris, and large

**Fig. 6.15.9** This fundus photo (A) and midphase angiogram (B) are of the left fundus of a patient with butterfly pattern dystrophy. The retinal pigment epithelium changes are much easier to notice in the angiogram than in the fundus photo.

choroidal vessels. Flecks in this disorder are whiter and more sharply delineated than those in fundus flavimaculatus.

Fluorescein angiography often highlights atrophy of the RPE, and the drusen appear more extensive than seen clinically. In advanced cases, a central scotoma is seen on visual field examination. OCT reveals a thickening and occasional elevation of the RPE-Bruch's membrane complex.<sup>59</sup> Dark adaptation is usually normal, as are the ERG findings.<sup>60</sup> The EOG findings are normal in the initial stages, but they become subnormal depending on the degree of macular involvement. Familial drusen also exhibit fundus autofluorescence.<sup>61</sup>

## **PATHOLOGY**

Histopathological examinations show round accumulations of hyaline in the pigment epithelium that are continuous with the inner layer of Bruch's membrane. The choroids and neural retina may show atrophy later on, although they appear normal in the earlier stages of the disease.

## **TREATMENT, COURSE, AND OUTCOME**

No known effective treatment exists for diseases in this category. If CNVs occasionally ensue, intravitreal injections of anti-vascular endothelial growth factor (VEGF) agents may improve or stabilize vision. As long as the drusen are relatively discrete and do not affect the fovea markedly, central vision usually is good. When basal laminar drusen coalesce to form a vitelliform cyst, a marked degradation in visual acuity can occur if the yolk degenerates into an atrophic scar. CNVs may occur occasionally.

## **PATTERN DYSTROPHY**

### **EPIDEMIOLOGY AND PATHOGENESIS**

Macular pattern dystrophies are a heterogeneous group of inherited retinal conditions that affect the RPE and are characterized by various patterns of brown, yellow, and orange pigment in the central macula. The incidence of this group of dystrophies has not been determined. There are several different characteristic patterns of pigmentation that are typically inherited in an autosomal dominant pattern.<sup>62,63</sup> Patients from the same family may have different patterns, and some patients can even change patterns or have different patterns in different eyes.<sup>64-66</sup> The pattern dystrophies have been found to be caused by various mutations in the

human RDS/peripherin (*PRPH2*) gene on chromosome 6p21.2.<sup>16,67,68</sup> The peripherin/RDS/*PRPH2* encodes for photoreceptor-specific transmembrane glycoprotein that may play a role in the development and maintenance of photoreceptor outer segments.<sup>67,69-72</sup> Interestingly, some forms of RP and other macular dystrophies are attributed to mutations in this same gene.<sup>72,73</sup>

## **OCULAR MANIFESTATIONS AND DIAGNOSIS**

The age of onset of pattern dystrophies is variable, with many patients remaining asymptomatic until the fifth decade of life; some patients remain asymptomatic throughout life. The pigmentary changes occur at the level of the RPE.<sup>63,74</sup> Drusen and yellow flecks are not characteristic of these dystrophies but pigment is. The clinical phenotypes have many characteristic pigment patterns, including butterfly dystrophy, reticular dystrophy, multifocal pattern dystrophy simulating fundus flavimaculatus, and fundus pulverulentus. The butterfly-shaped pattern dystrophy can most easily be appreciated by fluorescein angiography (FA) and autofluorescence (Fig. 6.15.9). As its name indicates, reticular dystrophy is marked by a reticular network of darkly pigmented lines in the macula. Note that adult vitelliform dystrophy (described earlier) is also included in pattern dystrophies, as this condition is often associated with mutation in the RDS/peripherin/*PRPH2* gene. Fundus pulverulentus is the rarest form, characterized by coarse pigment mottling of the central macula. This dystrophy can be especially difficult to differentiate from AMD and may often be misdiagnosed.<sup>75</sup>

## **PATHOLOGY**

Pattern dystrophies are caused by abnormalities in the RPE of the macula.<sup>74</sup> Reported histological findings are not well documented besides atrophy in the RPE and photoreceptor layers.

## **TREATMENT, COURSE, AND OUTCOME**

Most patients with pattern dystrophies present with only mild metamorphopsia or mildly diminished visual acuity. Many patients are only discovered to have the disorder during routine eye examination. Visual acuity usually remains good through the first five or six decades of life, but later in life it may lead to central macular atrophy, much like advanced AMD. Patients with pattern dystrophies have a small risk of developing choroidal neovascularization later in life.

## DOMINANT CYSTOID MACULAR EDEMA

### EPIDEMIOLOGY AND PATHOGENESIS

Dominant cystoid macular edema is a rare autosomal dominant disease mapped to chromosome 7q.<sup>76</sup> This macular dystrophy is unique in predominantly affecting only the inner nuclear layer of the retina. It is hypothesized that the gene mutation primarily affects Müller's cells, based on histopathological evidence.

### OCULAR MANIFESTATIONS AND DIAGNOSIS

These patients present with central cystoid macular edema, which can cause atrophic changes, and additional vision loss develops.<sup>77</sup> Of note, peripheral pigmentary changes may also be present. FA confirms capillary leakage, with a classic petaloid pattern of dye accumulation in the macula. ERG testing is typically within normal limits, but patients have been found to have decreased Arden (light peak-to-dark trough) ratios on EOG testing. In addition, abnormal dark adaptation studies have been noted for these patients.

### PATHOLOGY

These patients demonstrate macular cysts and disorganization and gliosis of the inner nuclear layer. In addition, they have focal Müller's cell necrosis, RPE and photoreceptor degeneration, epiretinal membrane formation, and abnormal deposition of basement membrane in the perivascular space.<sup>78</sup> Interestingly, the feature of Müller's cell necrosis is unique compared to cystoid macular edema secondary to other causes such as inflammation.

### TREATMENT, COURSE, AND OUTCOME

Dominant cystoid macular edema patients have the onset of symptoms typically in the third decade of life. This will usually slowly progress to cause moderate or severe vision loss. This condition can cause atrophic changes of the macula. No known effective treatment has yet been found.

## SORSBY'S MACULAR DYSTROPHY

### EPIDEMIOLOGY AND PATHOGENESIS

Sorsby's macular dystrophy is a rare, dominantly inherited disorder, with many similarities to AMD except for the age of onset. Sorsby's dystrophy is caused by a mutation in a tissue inhibitor metalloproteinase, *TIMP3*.<sup>79-82</sup> This protein is an important enzyme in the regulation and composition of the extracellular matrix and plays a role in wound healing, bone adaptation, and organ hypertrophy. *TIMP3* has a second function. It encodes a potent angiogenesis inhibitor by blocking the binding of VEGF to VEGF receptor-2. Studies have shown that *TIMP3* overexpression suppresses primary tumor growth and metastasis.<sup>83</sup> This enzyme is expressed in the RPE.<sup>84</sup>

*EFEMP1*, whose mutated gene is responsible for malattia leventinese, was discovered as a strong interacting protein with *TIMP3*. Both these dystrophies have similarities to AMD. This suggests the possibility of a common pathogenetic mechanism for these different forms of macular diseases.

A knockout mouse model of Sorsby's has been created.<sup>85</sup> The model features changes in Bruch's membrane and the RPE that may represent the primary clinical manifestations of Sorsby's.

### OCULAR MANIFESTATIONS AND DIAGNOSIS

Early in the disease, very fine drusen or a large confluent plaque of yellowish material may be noted beneath the central RPE. Then, typically at around 40 years of age, patients develop bilateral exudative maculopathy, which leaves heavily pigmented macular scars and areas of geographical atrophy.<sup>86</sup>

The ERG and EOG results usually are normal early, but decreased photopic and scotopic amplitudes can be seen late in the disease.

### PATHOLOGY

Light and electron microscopic studies show lipid-containing deposits between the basement membrane and the pigment epithelium and the inner collagenous layers of Bruch's membrane.<sup>87</sup>

## TREATMENT, COURSE, AND OUTCOME

Patients typically develop bilateral CNVs at an early age. Severe loss of central visual acuity results from extensive macular scarring related to CNVs. Like patients with AMD, CNVs can be successfully treated with anti-VEGF and has been treated with combined photodynamic therapy and intravitreal triamcinolone.<sup>88,89</sup> Nyctalopia also is a symptom late in the course of disease.<sup>86</sup>

## NORTH CAROLINA MACULAR DYSTROPHY

### EPIDEMIOLOGY AND PATHOGENESIS

North Carolina macular dystrophy (NCMD) is an autosomal dominant, congenital, completely penetrant macular degeneration first reported in a large family in North Carolina, after which the disease was inappropriately named.<sup>90,91</sup> It is rare but is found worldwide in over 40 families (Small, personal communication). Several separate affected families have been discovered in the United States, Europe, Central America, and China. Linkage analysis of the large family from North Carolina mapped the diseased gene to chromosome 6q16.<sup>2,92</sup> This chromosome 6 locus is now known as *MCDR1* (macular dystrophy, retinal subtype, first one mapped). Further genetic analysis reveals that families reported to have central areolar pigment epithelial dystrophy and central pigment and choroidal degeneration are branches of the same family from North Carolina.<sup>93</sup> Indeed, reports of various branches of the single family from North Carolina have resulted in this one disease being given seven different names during the last 25 years. Again, "lumping" diseases together has proven to be more accurate than "splitting." Although there are no accurate names properly describing the anatomic features or pathology, small macular dystrophy could be the best name for this enigmatic disease.<sup>94</sup>

### OCULAR MANIFESTATIONS AND DIAGNOSIS

The most striking features are the huge phenotypic variability within a family and the relatively good vision despite some with severe-appearing macular malformations. About one-third of affected individuals have a macular coloboma-like excavation resembling toxoplasmosis (Fig. 6.15.10A). There is clearly a well-demarcated area of absence of the RPE and choriocapillaris, typically with surrounding subretinal fibrosis—more so on the sharply shelving temporal edge than the more smoothly sloping nasal edge. The patient's fixation is typically on the nasal edge of the lesion rather than in the central area, where the fovea would be expected. This can be quite dramatic appearing on spectral-domain optical coherence tomography (SD-OCT) (Fig. 6.15.10B).

The highly variable expressivity occurs without any particular pattern. Genetic "anticipation" has been evaluated in these families and none was found (Small, personal communication). Some individuals express from birth only a few drusen centrally, whereas others have confluent drusen. Occasionally or rarely a patient will develop choroidal neovascularization with a disciform scar. These are the only patients who experience progressive moderate to severe vision loss and usually only in one eye. CNVs can also occur typically along the temporal edge of the "coloboma." Phenocopies of this disease include drusen of age-related macular degeneration, Best macular dystrophy, and toxoplasmosis. To clinically diagnose NCMD it is imperative to examine other family members in order to appreciate the full spectrum of the disease. Small and his coworkers have believed since 1992 that the *MCDR1* gene is involved in embryonic macular development. This would help explain why the vision is relatively good considering the severe-appearing lesions present in some. The ERG and EOG are normal, as is color vision. As expected, multifocal ERG recordings revealed significant amplitude reductions in the central retina.<sup>95</sup>

Small and colleagues initially mapped the *MCDR1* locus with the single large family from North Carolina to chromosome 6q12 in 1992.<sup>2</sup> His lab then ascertained additional families from around the world through personal examinations and many collaborators. Eventual linkage analysis of his entire database yielded a LOD score greater than 40, which is perhaps the highest LOD score ever recorded in human genetics.<sup>96-98</sup> Once NEXGEN sequencing became available, Small proceeded with targeted genomic sequencing of the 880 kilobases (Kb) region without any external funding. Overwhelmed with the bioinformatics, Stone and colleagues offered assistance to Small, and shortly thereafter the first mutations were found. Three point mutations were found 12 Kb into a noncoding region in a DNAS1 hypersensitivity binding site that affects regulation of expression

**Fig. 6.15.10 North Carolina Macular Dystrophy.** (A) Macular coloboma-like grade 3 maldevelopment of the macula in an 18-year-old woman with visual acuity of 20/40 (6/12). (B) Optical coherence tomography.

of the neighboring gene, the retinal transcription factor *PRDM13*.<sup>99</sup> A large duplication in the Belizean family also involves *PRDM13*. *PRDM13* is expressed in the fetal retina and dorsal spinal columns and is not expressed in adult tissues. This supports Small's original hypothesis that NCMD is due to a gene involved in the development of the primate macula (only primates have maculae). Because of the duplication, it would appear that the malformation of the maculae (and malformation includes the presence of drusen) is due to overexpression of *PRDM13*. Bowne and colleagues subsequently and independently found another large but different duplication involving *PRDM13* supporting Small and colleagues' earlier work.<sup>99,100</sup> Rosenberg and colleagues had previously mapped a Danish family with the NMCD phenotype to a chromosome 5 locus as MCDR3 showing the presence of some genetic heterogeneity.<sup>94</sup> Using this information from MCDR1, Small with Stone's group found a large duplication involving the *IRX1* gene, which is felt to be a causative mutation. Small and colleagues have a total of 40 families worldwide being studied, making "North Carolina macular dystrophy" a gross misnomer (Small personal communication).<sup>90</sup>

**Fig. 6.15.11 Atrophie Areata in a 37-year-old Man.** (Courtesy Fridbert Jonasson, University Department of Ophthalmology, Landspítalinn, Iceland.)

## PATHOLOGY

Small et al.<sup>101</sup> have studied the histopathology of a mildly affected family member who had bilaterally symmetrical confluent drusen in the central macula. Light microscopy demonstrated a discrete macular lesion characterized by focal absence of photoreceptor cells and RPE. Bruch's membrane was attenuated in the center of the lesion and associated with marked atrophy of the choriocapillaris. Adjacent to the central lesion, some lipofuscin was identified in the RPE.

## TREATMENT, COURSE, AND OUTCOME

The onset is congenital and nonprogressive except for the development of CNVMs. Visual acuity is usually much better than the appearance of the macula suggests. In general, vision is in the 20/20–20/200 range, with a median of 20/60. The CNVMs have been treated successfully with anti-VEGF injections (personal communication B. Bakall).

## ATROPHIA AREATA

## EPIDEMIOLOGY AND PATHOGENESIS

Atrophie areata, also known as helicoid peripapillary choroidal degeneration or Sveinsson chorioretinal atrophy, is a rare autosomal dominant disease reported only in Icelandic families mapped to chromosome 11p15.<sup>102</sup> The encoded protein TEAD1 may alter the expression of genes responsible for the structural and metabolic support of photoreceptors.<sup>103</sup> This is in concordance with electrophysiological testing, which demonstrates normal photoreceptor function but abnormal RPE function.

## OCULAR MANIFESTATIONS AND DIAGNOSIS

As with most inherited retinal diseases, atrophie areata is a bilateral, symmetrical maculopathy and has an early onset.<sup>102</sup> Marked choroidal atrophy radiates from the optic disc, with two or more ring-shaped extensions that do not follow the major retinal vessels (Fig. 6.15.11). The choroidal vessels drop out in areas of atrophy. This disorder often is associated with high myopic astigmatism. Anterior polar cataracts sometimes are seen in affected persons.

The fundus appearance is quite characteristic, particularly in advanced cases. Color vision usually is normal, and high myopia is a consistent feature.

## TREATMENT, COURSE, AND OUTCOME

Chorioretinal atrophy begins in childhood and is slowly progressive throughout life. Patients present with good visual acuity, but a gradual decline occurs in central vision as macular atrophy ensues.

## CONE DYSTROPHY

### EPIDEMIOLOGY AND PATHOGENESIS

Cone dystrophies are characterized by a specific degeneration of the cone photoreceptor cells. Most genetic causes of cone dystrophies are autosomal dominant, but all types of genetic inheritance have been reported. Small et al. reported a family from Tennessee with autosomal dominant cone degeneration that mapped to chromosome 17p12–13.<sup>104,105</sup> Although this was designated CORD 5 (cone–rod dystrophy 5, although it truly is a predominantly cone dystrophy with little to no rod impairment), the other families reported in the UK with CORD 6 have actually the same disease with similar mutations. In reality, CORD 6 is CORD 5, another misnomer in the literature. The causative gene in this family (and others) was found to be *GUCY2D*. In addition, cone dystrophies have been found to also be caused by mutations in the cone–rod homeobox (*CRX*) as well as the *ABCR* gene.<sup>10</sup>

### OCULAR MANIFESTATIONS AND DIAGNOSIS

Cone dystrophy patients usually present with progressive central acuity loss, color vision disturbances, and photophobia.<sup>106</sup> Patients have retinal changes ranging from subtle, diffuse macular pigment mottling only to focal atrophic macular changes often in a “bullseye” pattern (Fig. 6.15.12).<sup>106</sup> The ERG is essential for making the diagnosis, as it reveals selective diminution of the photopic “B” wave and decreased amplitudes of the 30 Hz flicker. The dark-adapted rod responses, on the other hand, are usually normal or mildly attenuated.<sup>106</sup> Multifocal ERG testing can also be helpful, as it will show low amplitudes or an abnormal foveal-to-parafoveal ratio caused by cone photoreceptors dysfunction. Color vision testing is helpful, which usually reveals dyschromatopsia. Visual field testing reveals full peripheral fields with bilateral central scotomata.

### TREATMENT, COURSE, AND OUTCOME

Cone dystrophies usually present during the first or second decades of life. Not unlike other macular dystrophies, cone dystrophy patients tend to have color vision loss early in the course of the disease. Visual acuity can range from 20/20 to hand movements. Patients experience progressive worsening of their disease with age. To date, this condition remains without a treatment, but gene therapy may be appropriate for these patients.

**Fig. 6.15.13 Central Areolar Choroidal Dystrophy.** (Courtesy Giuliani Silvestri.)

## CENTRAL AREOLAR CHOROIDAL DYSTROPHY

### EPIDEMIOLOGY AND PATHOGENESIS

Central areolar choroidal dystrophy (CACD) is a rare autosomal dominant macular disease mapped to chromosome 17p13.<sup>102,104</sup> Mutations to various loci in this region have been implicated in central areolar dystrophy.<sup>107</sup> Interestingly, several other inherited retinal diseases have been mapped to chromosome 17p, including autosomal dominant cone dystrophy, Leber’s congenital amaurosis, and ADRP. A mutation in the peripherin gene on chromosome 6 also has been associated with central areolar choroidal dystrophy, linking it with the chromosome 6 retinopathies also.<sup>16,107,108</sup> In addition, mutation in guanylate cyclase 2D gene (*GUCY2D*; MIM 600179) and also *GUCA1A* have been implicated in CACD.<sup>109,110</sup> This disease appears to be a primary dystrophy of either the choroidal vessels or the RPE, with secondary involvement of the choriocapillaris.

### OCULAR MANIFESTATIONS AND DIAGNOSIS

The disease is characterized by late onset of the phenotypic manifestations (midlife) with progression occurring over a 3- to 10-year period. It shows variable expressivity among family members.<sup>111</sup> Fundus examination early in the course of the disease reveals nonspecific granular hyperpigmentation of the fovea. Gradually, a sharply demarcated area of RPE atrophy with underlying loss of choriocapillaris leaves intermediate and large choroidal vessels visible (Fig. 6.15.13). As the disease progresses, the macular atrophic area expands in a slow, centrifugal manner. This can appear clinically similar to CORD 5 findings.

FA early in the course of the disease shows background hyperfluorescence from RPE atrophy. When the choriocapillaris becomes lost, this hyperfluorescence disappears, and the intermediate and large choroidal vessels are outlined sharply. The margins of the lesion show hyperfluorescence because of leakage from choriocapillaris at the edges. The ERG and EOG findings range from normal to severely abnormal.<sup>111</sup> Multifocal ERG recordings show significant macular dysfunction that extends beyond the atrophic areas seen clinically.<sup>112,113</sup>

### PATHOLOGY

Histological analysis of the affected area shows an atrophic, fibrosed area, with loss of RPE as well as photoreceptor cells and the underlying choriocapillaris.<sup>114</sup> The rest of the retina and choroid are normal outside of the atrophic zone.

### TREATMENT, COURSE, AND OUTCOME

Patients begin to complain of symptoms of central vision loss during the third to fourth decades of life. Progressive atrophy leads to severe visual dysfunction and absolute scotoma formation by the seventh decade. Some patients, however, may exhibit macular sparing with 20/20 visual acuity.

# Choroidal Dystrophies

Sandeep Grover, Gerald A. Fishman

# 6.16

## Definitions:

- Choroideremia is a progressive, bilateral, diffuse chorioretinal dystrophy with an X-linked recessive mode of inheritance.
- Gyrate atrophy of the choroid and retina is a progressive, bilateral, diffuse chorioretinal dystrophy with an autosomal recessive mode of inheritance.

## Key Features

### Choroideremia

- Involvement of the choroid, retinal pigment epithelium, and retinal photoreceptors.
- Nyctalopia.
- Midperipheral and, subsequently, far peripheral visual field loss.

### Gyrate Atrophy

- Chorioretinal lesions of atrophic appearance with scalloped margins.
- Nyctalopia.
- Midperipheral and peripheral visual field loss.
- Frequently, they develop cataracts.

## Associated Features

- Choroideremia: often initial macular sparing; characteristic findings in female carriers.
- Gyrate atrophy: systemic hyperornithinemia associated with an ornithine aminotransferase enzyme defect.

## INTRODUCTION

Choroidal dystrophies are a group of progressive, hereditary disorders that are characterized by clinically apparent retinal pigment epithelial (RPE) and choroidal atrophy. Krill and Archer<sup>1</sup> classified such dystrophies into two groups, one with a more regional involvement and the other with a diffuse involvement of the fundus. The regional dystrophies are subclassified further based on the initial or predominant site of the degenerative changes (macular, central areolar, peripapillary, or a combination) and the severity of involvement (involving only the choriocapillaris or, in addition, the larger choroidal vessels). Choroideremia and gyrate atrophy of the choroid and retina represent diffuse forms of choroidal dystrophies. Progressive bifocal chorioretinal atrophy<sup>2</sup> phenotypically shows a regional involvement, but there is a diffuse reduction of retinal function.

## CHOROIDEREMIA

## INTRODUCTION

Choroideremia is an X-linked recessive, bilateral, progressive chorioretinal dystrophy that is characterized by a marked loss of vision at night and progressive loss of peripheral visual fields.

## EPIDEMIOLOGY AND PATHOGENESIS

The exact pathogenesis of the degenerative changes observed in patients and the cells primarily affected in choroideremia are yet to be defined with certainty. In the past, it was thought that this disease was caused primarily by degeneration of RPE cells, the choroid, or both, with photoreceptors degenerating secondarily. It has been suggested that the primary defect

may be in the rod photoreceptor cells of the retina.<sup>3</sup> It has also been proposed that there may be independent degeneration of RPE cells and photoreceptor cells, based on a conditional knockout mouse model.<sup>4</sup> A recent multimodal imaging of photoreceptor structure in choroideremia showed remnants of cone inner segments within “outer retinal tubulations” (ORTs) and the continuity of the ORTs with the preserved retina, thereby suggesting degeneration of RPE earlier than the photoreceptors.<sup>5</sup>

The choroideremia gene (CHM) was isolated by positional cloning techniques and localized to the long arm of the X chromosome (Xq21).<sup>6,7</sup> The CHM gene encodes the Rab escort protein-1 (REP-1)<sup>8</sup> of Rab geranylgeranyl transferase, a two-component enzyme (components REP-1 and REP-2) that modifies Rab proteins. Rab proteins are low-molecular-weight guanosine triphosphatases that regulate intracellular vesicular transport. For Rab proteins to bind to membranes, they undergo lipid modification with the addition of 20 carbon units to the carboxy terminal of the protein, a process known as geranylgeranylation. Of interest, the CHM gene is expressed not only in ocular tissues but also in various cells of nonocular origin. However, CHM gene dysfunction affects only the retina. The proteins REP-1 and REP-2 are 75% identical, and their functions are mutually redundant. The functioning of the majority of the cells in the body that have a REP-1 deficiency can be taken over by REP-2 and, hence, can function adequately. However, the retina has a major Rab protein, Rab 27, which is prenylated more efficiently by REP-1 than REP-2.<sup>9</sup> Since all mutations known so far in the CHM gene create stop codons and, hence, an absence of the gene product REP-1, there is progressive chorioretinal degeneration in patients with choroideremia.<sup>10</sup>

## OCULAR MANIFESTATIONS

A majority of patients with choroideremia present with progressive impairment of night vision. It usually begins in the first decade of life, although the onset may be delayed. Some patients can, however, have midperipheral visual field loss. The clinical features, including the rate of progression, can show both interfamilial and intrafamilial variability.

The ocular findings in the anterior segment are unremarkable. Posterior subcapsular changes in the lens develop more frequently than in the general population.<sup>11</sup> Even those patients who do not show clinical cataract changes may have subclinical lens changes as demonstrated indirectly by increased light scatter.<sup>12</sup>

Initial fundus changes most often begin in the midperipheral retina in the form of patches of pigment mottling and hypopigmentation. Nummular areas of patchy RPE and choroidal atrophy can develop subsequently in the midperipheral retina (Fig. 6.16.1). In the intermediate stages of the disease, the atrophy of the RPE and choriocapillaris becomes more diffuse, while the intermediate and the larger choroidal vessels remain relatively more preserved (Fig. 6.16.2). As the disease progresses, both the intermediate- and large-sized choroidal vessels become more atrophic, which exposes the underlying sclera. The macula is often initially relatively spared and is visible as a remaining island of choriocapillaris in the midst of surrounding white sclera (Fig. 6.16.3). The macula can be relatively well preserved even in the late stages of the disease. Only in the more advanced stages do the retinal arterioles become attenuated, while the optic disc does not tend to become as pale or waxy pale as occurs in patients with retinitis pigmentosa.

The loss of visual field often corresponds to the clinically discernible areas of chorioretinal atrophy. Visual field examination initially shows a slightly restricted peripheral field, midperipheral scotomas, or both. With time, these scotomas coalesce to form a ring scotoma.<sup>13</sup> The fields progressively constrict and finally leave a small central island. The visual acuity often is not notably affected and remains favorable until the seventh decade of life or even later.<sup>14</sup> According to another study, there is

**Fig. 6.16.1 Fundus Changes Found in Choroideremia.** Nummular areas of retinal pigment epithelial and choroidal atrophy in the midperipheral retina are shown.

**Fig. 6.16.4 Peripheral Fundus Changes in a Carrier of Choroideremia.** Note the radial bands of hyperpigmentation and some pigment clumping.

**Fig. 6.16.2 Fundus Changes of the Right Eye in a Patient With an Intermediate Stage of Choroideremia.** Note the diffuse changes of the retinal pigment epithelium and prominent choroidal vessels.

**Fig. 6.16.3 Fundus Changes in the Right Eye in a Patient With Late-Stage Choroideremia.**

a significant decline in visual acuity after age 50 years.<sup>15</sup> Visual acuity may be decreased because of a degenerative maculopathy or the development of posterior subcapsular cataracts. A careful refraction is prudent, because such patients may have various degrees of myopia.

The female carriers are typically asymptomatic. There is a wide spectrum of clinical fundus appearance, which ranges from a fundus of normal appearance to a full-blown picture of choroideremia, as in an affected male. Characteristically, however, pigmentary changes in the fundus, described as *moth-eaten* in appearance, occur predominantly in the midperipheral retina.<sup>16</sup> Areas of hyperpigmentation may be present as radial bands that extend from the midperiphery toward the ora serrata (Fig. 6.16.4). The visual acuity may be decreased and visual fields reduced, depending on the extent of involvement of the photoreceptors. Usually these defects appear late, if at all, and are often mild. Most carriers do not show any electroretinographic amplitude reductions, although those who have more advanced fundus degenerative changes can show appreciable amplitude reductions.

## DIAGNOSIS AND ANCILLARY TESTING

The clinical fundus features are usually diagnostic in the intermediate and late stages of the disease. Good central visual acuity and slowly progressive visual field changes aid in the diagnosis. Both the electroretinogram and electro-oculogram can show marked impairment.<sup>16</sup> The electroretinogram may rarely be normal in amplitude initially (Fig. 6.16.5) or occasionally show only mild impairment in the very early stages. However, with the progression of the disease, there is progressive loss of retinal function (Fig. 6.16.6). The fundus findings initially may be normal or only minimally abnormal (Fig. 6.16.7). Once fundus changes become discernible, however, the electroretinogram is affected, usually notably. It often shows markedly reduced isolated rod responses with prolongation of rod b-wave implicit times in affected men. However, the isolated cone responses are initially either normal or moderately reduced in amplitude, with a delayed b-wave implicit time. The electro-oculogram is markedly abnormal in men with choroideremia<sup>1</sup>; the degree of electro-oculogram abnormality in carriers, although usually normal, varies.

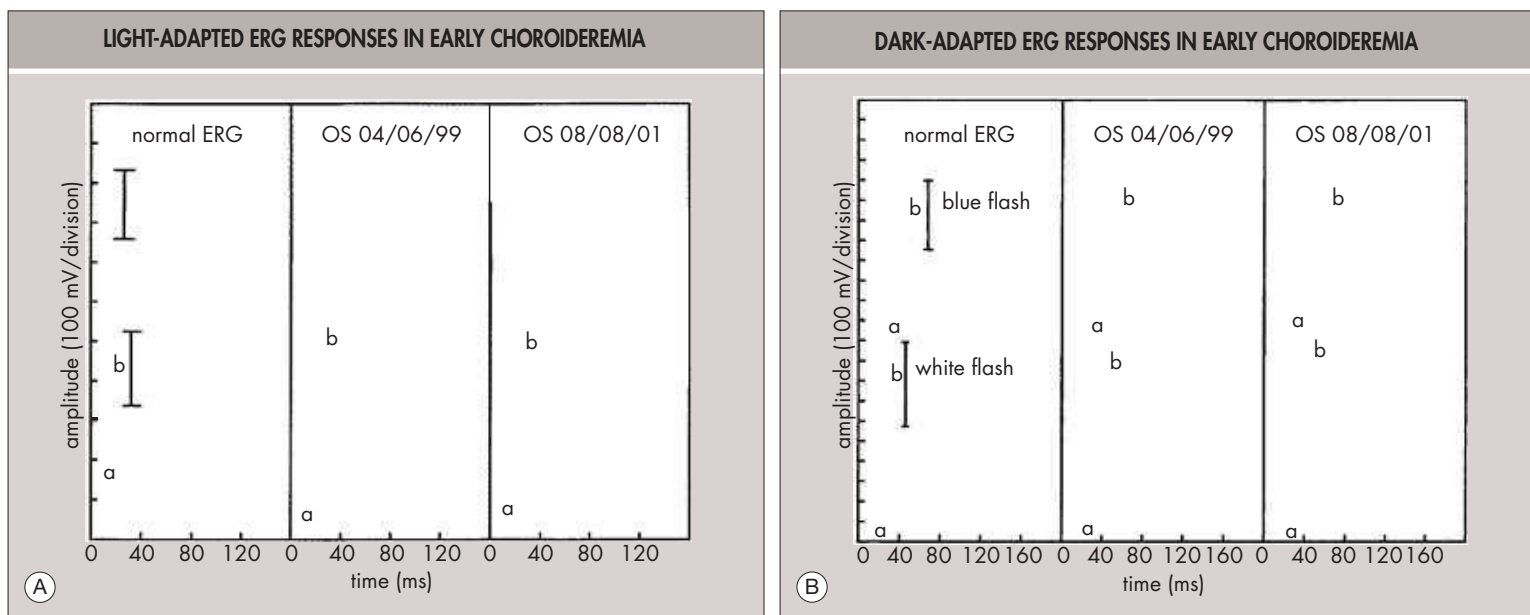

Dark adaptation testing often shows elevated thresholds. In the early stages, only the rod portion of the curve is affected, while cone thresholds subsequently also become elevated.

Spectral-domain optical coherence tomography (SD-OCT) can show cystic macular lesions (Fig. 6.16.8A)<sup>17</sup> and peripapillary nerve fiber layer defects (Fig. 6.16.9),<sup>18</sup> including thickening and thinning in various areas in some patients with choroideremia.

Fluorescein angiography is not useful in the diagnosis of choroideremia. It can, however, define the extent of choriocapillaris atrophy more accurately than ophthalmoscopy. Fluorescein angiography also may be superior to ophthalmoscopy in defining the extent of degenerative changes of the RPE, evident from hyperfluorescence seen on the angiogram.

The clinical diagnosis of choroideremia in the majority of male patients can be confirmed by an immunoblot analysis with anti-REP-1 antibody.<sup>19</sup>

**Fig. 6.16.5** Electoretinographic recordings from a male patient with choroideremia at ages 9 and 11 years showing normal light-adapted flicker and single flash (A) and dark-adapted rod-isolated and maximal (B) responses.

**Fig. 6.16.6** Electoretinographic Recordings From a Male Patient With Choroideremia (as Shown in Fig. 6.16.3) Showing Progressive Decline in Light- and Dark-Adapted Responses.

The value of this test is based on the knowledge that all genetic mutations identified so far create stop codons that result in the absence of REP-1. The predictive value of this test, however, has not yet been established.<sup>19</sup> Also, female carriers cannot be identified with this technique, because their REP-1 expression is not totally absent.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for choroideremia includes other night-blinding disorders, particularly retinitis pigmentosa. Fundus features of a pale optic disc, attenuated retinal arterioles, typical bone-spicule-like pigmentation, and a higher prevalence of posterior subcapsular cataracts associated with retinitis pigmentosa usually helps differentiate the latter disease from choroideremia. Nevertheless, some patients who have the X-linked form of retinitis pigmentosa, who can show higher degrees of myopia and prominent choroidal vessels, may have a phenotypic similarity to patients who have choroideremia. However, patients who have X-linked retinitis pigmentosa

have a reduction in central visual acuity early in the course of their disease, while patients with choroideremia do not characteristically manifest bone-spicule-like pigment clumping.

Patients who have ocular albinism may show some degree of phenotypic similarity to those with choroideremia; however, absence of nyctalopia, presence of nystagmus, iris transillumination defects, and normal electoretinographic amplitudes help to differentiate these two disorders.

Features distinguishing gyrate atrophy of the choroid and retina from choroideremia include autosomal recessive inheritance, well-demarcated, scalloped areas of chorioretinal atrophy, and association of hyperornithinemia with the former. It sometimes may be difficult to differentiate end-stage gyrate atrophy from an advanced case of choroideremia.

Generalized choroidal atrophy, which may show phenotypic similarities to an intermediate stage of choroideremia, is inherited in an autosomal dominant or occasionally autosomal recessive fashion. The various regional types of choroidal atrophies usually cause a milder visual dysfunction and, in general, can be differentiated easily without notable difficulty.

Another form of a diffuse choroidal dystrophy, progressive bifocal chorioretinal atrophy 2, is an autosomal dominant dystrophy. Its phenotype includes an involvement of the macula from birth, and hence nystagmus and reduced central visual acuity, a relatively higher incidence of retinal detachment and diffuse reduction of rod and cone responses on electroretinography. The phenotype of this disease has a distinctly different fundus appearance, time of onset, and genetics than are observed in choroideremia.

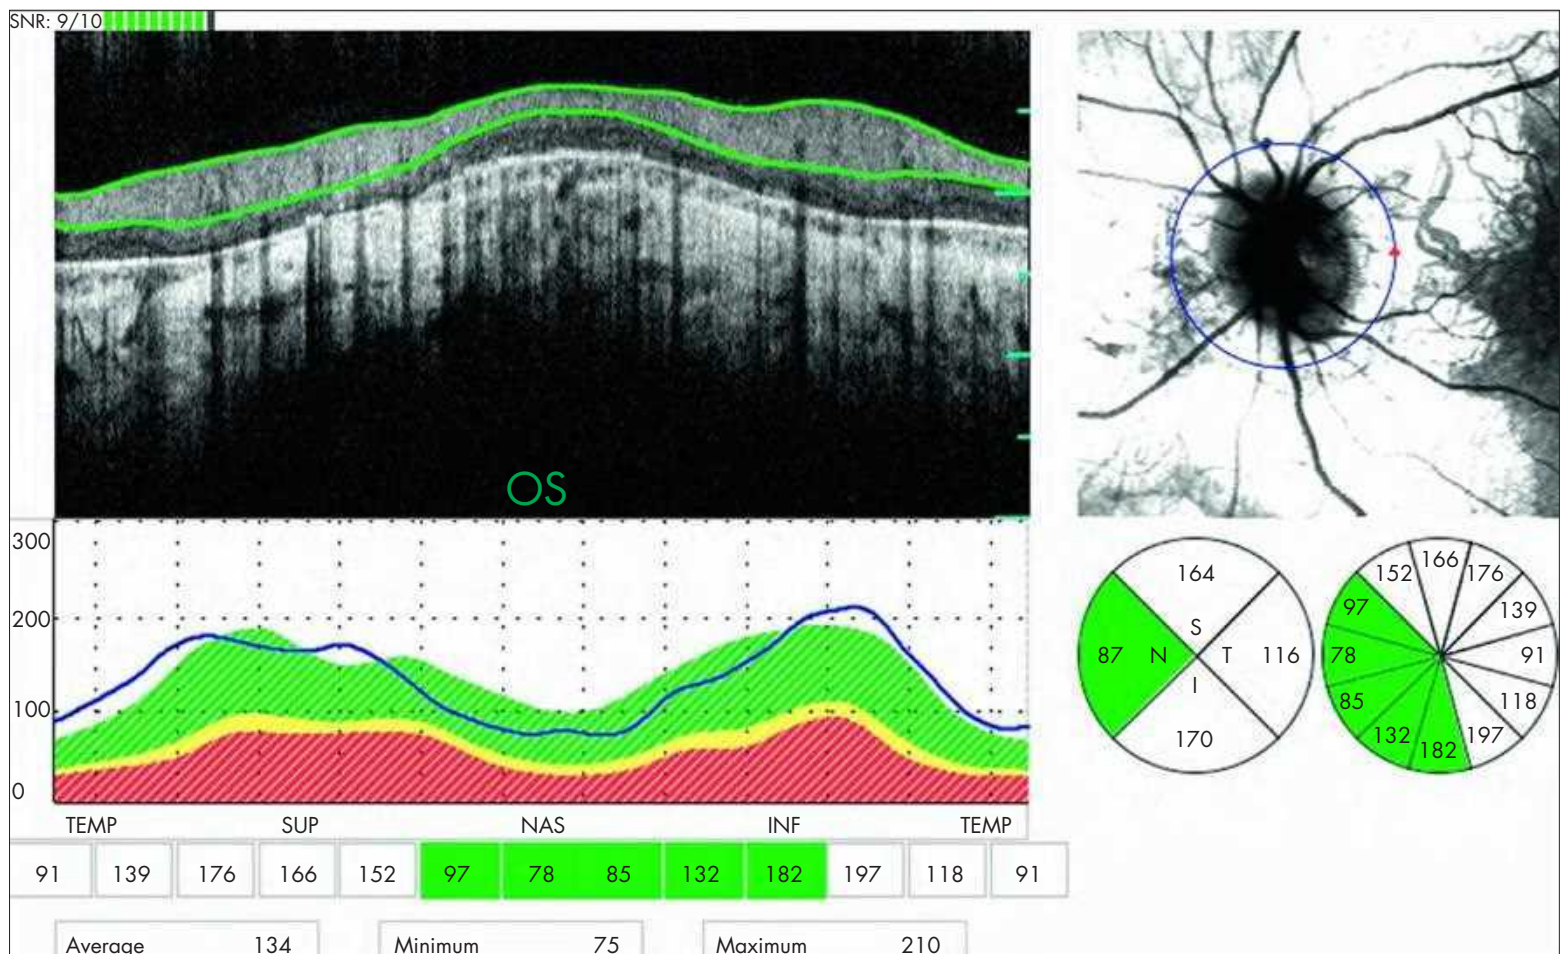

Myopic retinal degeneration sometimes may mimic choroideremia. However, the myopic degeneration usually is not as diffuse as the lesions

**Fig 6.16.7** Fundus Photograph of the Right Eye of the Same Patient as in Fig. 6.16.5 at Age 11 Years, Showing Normal Optic Discs and Retinal Vessels. Also shown is a mild to moderate degree of pigment mottling anterior to the vascular arcades.

**Fig. 6.16.8** Serial images of spectral-domain optical coherence tomography from a patient with choroideremia, showing cystic macular changes and increased macular thickness (A). The other two panels show resolution of cystic changes and decrease in macular thickness 6 months (B) and 12 months (C) after initiation of treatment with topical 2% dorzolamide ophthalmic solution.

**Fig. 6.16.9** Spectral-Domain Optical Coherence Tomography Image Showing the Retinal Nerve Fiber Layer (RNFL) Thickness in a Patient With Choroideremia. It shows some segments (green) where the RNFL thickness is within the normal range and some areas (white) where the RNFL thickness is more than normal.

of choroideremia, and patients with myopic degeneration do not characteristically complain of night blindness.

## SYSTEMIC ASSOCIATIONS

Isolated reports show the association of a choroideremia-like phenotype with mental deficiency, acrokeratosis, anhidrosis, and skeletal deformity; uveal coloboma; obesity and congenital deafness; congenital deafness and mental retardation; hypopituitarism; distal motor neuropathy; and nystagmus, myopia, dental deformities, optic nerve head drusen, and microblepharia.

## PATHOLOGY

In male patients with choroideremia, light microscopy shows widespread chorioretinal atrophy, especially of the choriocapillaris, along with degenerative changes in the RPE, outer retinal layers (especially the photoreceptors), and larger choroidal vessels. A graded atrophy occurs: The equatorial area is most affected while the macular, peripapillary, and ora serrata areas are relatively spared. In the late stages, the far periphery and the central regions also may be severely involved. Retinal bipolar and ganglion cells appear normal. Electron microscopy shows extensive loss of photoreceptors and RPE, especially away from the macula. End-stage disease can show widespread neural retinal gliosis and atrophy.

A histopathological study<sup>3</sup> in an 88-year-old choroideremia carrier showed patchy areas of degeneration of photoreceptors and RPE cells that were not necessarily concordant. The choriocapillaris was normal except where corresponding to areas of severe retinal degeneration, as reported previously. However, immunofluorescence analysis localized the CHM gene product (REP-1 with a mouse monoclonal antibody) to the rod cytoplasm and amacrine cells but not in the cones.<sup>3</sup> This suggests that the primary site of the disease may be in the rods rather than RPE or choroid. This labeling, which was seen in small vesicles in the rod cytoplasm, is consistent with the association of REP-1 with intracellular vesicular transport.

## TREATMENT, COURSE, AND OUTCOME

A phase I/II clinical trial with subretinal injection of an adeno-associated viral gene vector encoding for REP1 (AAV-REP1), showed that this was safe and reported significant visual acuity improvement in 2 of 6 patients enrolled.<sup>20</sup> This improvement in visual acuity was sustained at 3.5 years.<sup>21</sup> Several other similar treatment trials are underway in the United States ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02341807) Identifier: NCT02341807) and Canada ([ClinicalTrials.gov](https://clinicaltrials.gov/ct2/show/study/NCT02077361) Identifier: NCT02077361).

The cystic macular changes associated with choroideremia, as seen by SD-OCT, can diminish or resolve when treated with topical 2% dorzolamide, leading to decreased macular thickness (see [Fig. 6.16.8B–C](#)) in at least some patients.<sup>22</sup>

## GYRATE ATROPHY

### INTRODUCTION

Gyrate atrophy of the choroid and retina is a slowly progressive chorioretinal dystrophy, inherited in an autosomal recessive manner. It is characterized by discrete areas of chorioretinal atrophy in the midperipheral retina. These are sharply demarcated from the more posterior retina, which is initially of normal appearance. This dystrophy is associated with hyperornithinemia to levels 10–15 times above normal, shown to be caused by a deficiency of ornithine ketoacid aminotransferase, also known as ornithine aminotransferase (OAT). This enzyme depends on a cofactor, pyridoxal phosphate (vitamin B<sub>6</sub>).

### EPIDEMIOLOGY AND PATHOGENESIS

Simell and Takki<sup>23</sup> in 1973 were the first to report the finding of hyperornithinemia with gyrate atrophy. Sengers et al.<sup>24</sup> first reported a deficiency of the mitochondrial matrix enzyme OAT in patients who have gyrate atrophy. Ornithine, a nonessential amino acid, is an intermediate compound in the formation of urea. The major pathway for utilization of ornithine is by enzymatic conversion into glutamic- $\gamma$ -semialdehyde by OAT, a vitamin B<sub>6</sub>-dependent enzyme, and subsequently to proline. OAT has been found with high activity in the retina, liver, and kidney.

**Fig. 6.16.10 Fundus Changes in the Left Eye of a Patient With an Intermediate Stage of Gyrate Atrophy of the Choroid and Retina.** Note the well-demarcated, scalloped areas of atrophy.

Since OAT is dependent on cofactor B<sub>6</sub>, treatment with oral vitamin B<sub>6</sub> has been tried. Patients who have gyrate atrophy are categorized into two groups, depending on a lowering of plasma ornithine levels in response to vitamin B<sub>6</sub>. The vitamin B<sub>6</sub>-responsive patients, although considerably fewer in number than nonresponders, appear to have a milder disease and better visual function than the nonresponsive group.

The human OAT gene has been cloned and mapped to 10q26.<sup>25</sup> An OAT-deficient mouse model (Oat<sup>-/-</sup>) has been developed by gene targeting that has serum ornithine levels 10–15 times the normal, as in patients with gyrate atrophy.<sup>26</sup> This has improved the potential for a better understanding of the pathogenesis and possible therapeutic outcome of this disease.

## OCULAR MANIFESTATIONS

Patients with gyrate atrophy of the choroid and retina develop nyctalopia during the second to third decade of life. Initially it is mild to moderate in severity and slowly progressive. The earliest appearance may occur in the form of a restriction in peripheral field. Usually, visual acuity is preserved until a later stage. Visual acuity may be decreased from involvement of the macula by the disease itself or secondarily from cystoid macular edema or cataracts.

The fundus shows atrophy of the RPE and choriocapillaris during the earlier and intermediate stages, with sharply demarcated scalloped areas of atrophy ([Fig. 6.16.10](#)) and a tendency for pigment clumping to occur at the margins. The atrophy usually starts in the midperipheral and peripheral areas, often referred to as a *garland-shaped* fashion, and then progresses centrally as well as peripherally. Ultimately it involves the entire fundus, including the peripapillary area, with relative sparing of the macula. With progressive atrophy, the larger choroidal vessels are also involved. The optic disc and retinal arterioles usually are normal until the later stages.<sup>16</sup> Posterior vitreous detachment and epiretinal membranes with cystoid macular edema have been observed with gyrate atrophy of the choroid and retina.<sup>27</sup>

Visual field defects correspond to the atrophic areas in the choroid. The field loss begins in the midperipheral area as regionally dense scotomas, which eventually coalesce to form a ring scotoma. Progressive field loss ultimately leaves the patient with only small residual central fields.

Moderate-to-marked myopia is found in most patients, and lens changes are seen in almost all patients who have this disease.<sup>28</sup> Posterior sutural and subcapsular cataracts and, in isolated cases, anterior subcapsular plaque-like cataracts have been described.<sup>29</sup>

## DIAGNOSIS AND ANCILLARY TESTING

A history of night blindness and the typical fundus feature of scalloped areas of atrophy of the RPE and choroid are suggestive of the diagnosis. The electroretinogram is subnormal in the early stages, with marked reduction or nondetectable a- and b-wave responses in the later stages. The rod responses are affected more severely in the early stages, but later both rods and cones become affected.<sup>30</sup> Some patients also have a delayed cone implicit time response when tested using a 30-Hz flicker stimulus.<sup>30,31</sup> The electro-oculogram is affected mildly or not at all in very early stages of the disease.<sup>30</sup> However, with progression of the disease, electro-oculogram

**Fig. 6.16.11 Fundus Changes in the Right Eye of a Patient With Choroideremia.** The scalloped areas of atrophy resemble the lesions found in gyrate atrophy of choroid and retina.

light-peak to dark-trough ratios become markedly reduced. Overall, the electroretinographic responses, including oscillatory potentials and electro-oculogram light-peak to dark-trough ratios are better maintained in vitamin B<sub>6</sub>-responsive patients.<sup>30</sup> Dark adaptation curves may show a slightly prolonged cone-rod break time. In a vitamin B<sub>6</sub> responder or in early childhood, when the disease is not as severe, notably less extensive changes occur in dark adaptation function. However, in later stages of the disease, more marked elevation of cone, rod, or both thresholds develop.<sup>30</sup>

Fluorescein angiography, not unexpectedly, shows RPE transmission defects in the areas of chorioretinal atrophy. These areas of transmission defects often are larger than the clinically visible atrophic areas.

High ornithine levels are found in the urine, plasma, aqueous humor, and cerebrospinal fluid of these patients, often elevated to 10–20 times the normal levels. No evidence exists of any correlation of age or severity of involvement with the concentration of ornithine in plasma.<sup>32</sup> The 24-hour urine creatine excretion is normal.

## DIFFERENTIAL DIAGNOSIS

Gyrate atrophy of the choroid and retina is diagnosed by means of the typical fundus feature of scalloped areas of chorioretinal atrophy, an autosomal recessive inheritance, and hyperornithinemia. However, a gyrate atrophy-like fundus phenotype with a possible autosomal dominant inheritance pattern and normal plasma ornithine levels has also been described.<sup>33</sup> Gyrate atrophy also can show certain phenotypic similarities to choroideremia, myopic degeneration, and hereditary choroidal atrophy. It is mainly in its later stages that gyrate atrophy of the choroid and retina clinically may most resemble the retinal findings seen in choroideremia. However, in earlier stages of the disease, patients who have choroideremia may show scalloped or nummular areas of RPE and choroidal atrophy (Fig. 6.16.11). Typical retinitis pigmentosa usually can be differentiated from gyrate atrophy, but atypical retinitis pigmentosa sometimes may show certain phenotypic similarities. Bone-spicule pigment in the retina and attenuated retinal arterioles at an earlier stage aid in the diagnosis of retinitis pigmentosa. In gyrate atrophy, the pigment clumps usually are more dense and associated with the atrophic lesions.<sup>32</sup>

## SYSTEMIC ASSOCIATIONS

Electromyograms are abnormal in most tested patients, although only a few complain of slight muscle weakness. Electromyographic observations include a myopathic pattern of short-duration, low-amplitude motor unit action potentials, and increased polyphasic potentials. Muscle biopsy shows atrophic type 2 muscle fibers with tubular aggregates visible on electron microscopy. Abnormal electrocardiographic features may include a broad P-wave, prolonged QT interval, and flattening of the T-wave. Electroencephalograms also may be abnormal in some patients.<sup>31,32</sup> The

changes include an increase in slow activity, focal slow-wave abnormalities, and focal sharp waves.<sup>32</sup>

Various rare associations of a clinical picture that resembles gyrate atrophy have been seen with microcephaly, spinocerebellar ataxia, subluxation of the lens, pituitary dysfunction, and congenital muscular dystrophy. All of these associations were found with normal levels of plasma ornithine.

Reports exist of fine, sparse hair with patches of alopecia, skeletal muscle abnormalities, hepatic mitochondrial changes, and subnormal intelligence. Massive cystinuria and lysinuria with hypermetropia and diabetes also have been observed with gyrate-like atrophy. Chorioretinal lesions that resemble gyrate atrophy have been described in patients with normal plasma ornithine levels.<sup>33</sup>

## PATHOLOGY

Limited information on pathological findings is available on patients with gyrate atrophy.<sup>34</sup> The atrophic areas in the midperipheral retina show a marked atrophy of the choroidal vessels, including the choriocapillaris, RPE, and photoreceptors. The regions of clinically normal appearance in the posterior pole show focal areas of photoreceptor cell loss. The RPE at the posterior pole, however, has been reported to be hyperplastic. The photoreceptors show a shortening of their outer segments in the transitional area and are absent in the atrophic areas.<sup>34</sup> Histological examination of cataractous lenses shows markedly widened spaces at the posterior sutures, filled with denatured proteins.<sup>28</sup>

Electron microscopy shows abnormal mitochondria in the corneal endothelium, smooth muscle of the iris and ciliary body, and epithelium of the ciliary body.<sup>34</sup> Mitochondrial abnormalities include enlarged and dilated mitochondria with an electron-lucent matrix and disruption of cristae. Slight mitochondrial changes are observed in those photoreceptors that look normal structurally but are close to the area of chorioretinal atrophy. Dilated mitochondria are present mainly in rod ellipsoids but also in cone ellipsoids. The mitochondria in the RPE initially are normal.<sup>34</sup>

Histopathological studies in the OAT-deficient mouse model showed earliest changes in the RPE cells in the form of occasional necrotic cells with pale cytoplasm and swollen organelles at 2 months of age. By 7 months, these RPE cells were engorged with phagocytosed outer segment membranes. Photoreceptor cells, which were normal at 2 months of age, lost 33% of their total number and underwent 60% reduction of their outer segment length by 10 months.<sup>26</sup>

## TREATMENT, COURSE, AND OUTCOME

Since ornithine is produced from other amino acids, mainly arginine, some investigators advocate that patients be restricted to a rigid schedule of a low-protein diet, including near-total elimination of arginine, with supplementation of essential amino acids. Administration of high doses of vitamin B<sub>6</sub> has reduced the plasma ornithine level in a limited number of such patients. The results of these forms of treatment have been controversial. Short-term treatment has not shown any convincing evidence of improvement or arrest of the chorioretinal degeneration.<sup>35</sup> However, a long-term study of an arginine-restricted diet in six pairs of affected siblings was encouraging,<sup>36</sup> because it showed that a substantial reduction of ornithine levels occurred when such patients were fed an arginine-restricted diet over a period of 5–7 years.<sup>37</sup> Two of these six sibling pairs, when followed for 16–17 years, showed that the younger sibling in each pair (who was started on this diet at an earlier age than the older sibling) showed a slower progression of chorioretinal lesions and, to a lesser extent, the progressive loss of retinal function. A long-term study in adults also suggested that as long as the plasma ornithine levels can be maintained below an average of 5.29–6.61 mg/dL (about six times the normal range), it may slow the progression of disease as measured by sequential electroretinography.<sup>38</sup> These studies suggest that an arginine-restricted diet may cause a decrease in the progression of the chorioretinal degeneration. Consistent with these observations, correction of ornithine accumulation by an arginine-restricted diet in the Oat<sup>-/-</sup> mouse model entirely prevented retinal degeneration.<sup>39</sup> This suggests that it may not be necessary to restore the activity of the OAT enzyme to metabolize the accumulating ornithine for treating this condition but instead to restrict arginine, the substrate from which ornithine is formed.<sup>39</sup>

As with other inherited retinal degenerative disorders, a better understanding of the pathogenic mechanisms by which the retinal cells degenerate in patients who have various choroidal dystrophies will ultimately lead to more effective treatment strategies in the future.

# Hereditary Vitreoretinopathies

Alan E. Kimura

# 6.17

**Definition:** A group of rare inherited disorders with primary manifestations that include vitreous and retinal degeneration.

## Key Features

- Range of developmental abnormalities affecting the retinal vasculature through the Wnt signaling pathway in Norrie's disease and familial exudative vitreoretinopathy.
- Range of structural abnormalities in vitreous due to known mutations in Stickler's syndrome and in retina due to known mutations in X-linked recessive juvenile retinoschisis.

## Associated Features

- Autosomal dominant or X-linked recessive inheritance patterns.
- Loss of b-wave on electroretinography in X-linked recessive juvenile retinoschisis.
- Retinal pigment epithelial hyperplasia or atrophy in autosomal dominant vitreoretinopathy.
- Vitreoretinal traction and retinal detachment in Norrie's disease, familial exudative vitreoretinopathy, X-linked juvenile retinoschisis, and Stickler's syndrome.
- Epiphyseal dysplasia with premature degeneration of weight-bearing joints in Stickler's syndrome.
- Osteopenia or osteoporosis in autosomal dominant familial exudative vitreoretinopathy.
- Deafness and mental retardation in many cases of Norrie's disease.

## INTRODUCTION

The hereditary vitreoretinopathies are a diverse group of disorders. Research into these rare diseases continues to illuminate the breadth of mechanisms that can lead to blindness.

Stickler's syndrome is the result of abnormalities in a key structural building block of the connective tissue of the eye, collagen IIa, as well as collagen IXa and collagen XIa. X-linked, recessive, juvenile retinoschisis features abnormalities in the protein retinoschisin, which is believed to play an integral role in cell–cell adhesion within the retinal tissue. Autosomal dominant vitreoretinopathy (ADVIRC) is one of five diseases caused by mutations in the bestrophin gene. The phenotypic range of the bestrophinopathies includes Best disease and ADVIRC. Familial exudative vitreoretinopathy (FEVR) and Norrie's disease are now increasingly understood to share ligand–receptor elements in the important Wnt signaling pathway that is central to vascular development within the eye.

The exact role of the vitreous body in these diseases is unknown and has received little attention. Sebag<sup>1</sup> studied the anatomy of the vitreous body and its role in retinal diseases. Historically, vitreous was believed to play a passive role in the maintenance of the volume of the eye and surgically was avoided because of historically poor outcomes when disturbed. However, therapeutic vitrectomy with refinements in modern guillotine cutters became safe and accepted. As a result of considerable surgical experience, our management of vitreoretinal traction in hereditary retinal diseases is improving.

For each of the entities discussed in this chapter, a McKusick identification number is given. *McKusick's Mendelian Inheritance in Man* is a textbook that is a catalog of genes and genetic disorders in man.<sup>2</sup> The book and online version (*Online Mendelian Inheritance in Man*)<sup>3</sup> are good references for discussing genetic diseases among researchers and clinicians.

Recent advances in molecular biology continue to shed light not only on genes specific to the retina but increasingly reveal the complexity of larger developmental pathways and their exquisite regulation.

## STICKLER'S SYNDROME

### INTRODUCTION

Stickler's syndrome is also known as hereditary arthro-ophthalmopathy. Its inheritance pattern is autosomal dominant with complete penetrance but widely variable expressivity. It is a progressive disorder with a high risk of both ocular and systemic morbidity. The clinical spectrum of affected patients who have Stickler's syndrome includes high myopia, retinal detachments, and premature degenerative changes of cartilage.

### EPIDEMIOLOGY AND PATHOGENESIS

Stickler's syndrome is the most common autosomal dominantly inherited connective tissue disorder in the American Midwest.<sup>4</sup> The strongest case for the argument that vitreous body abnormalities cause retinal pathology arises primarily in Stickler's syndrome. It is hypothesized that the vitreous degeneration is a direct effect of mutations in a structural protein, procollagen II. A significant advance in our understanding of Stickler's syndrome (McKusick No. 120140) was the discovery of a type II collagen gene (COL2A1) mutation on the long arm of chromosome 12 in affected pedigrees. The gene product is a building block in various types of tissue. Structural alterations in the highly ordered vitreous body that arise from COL2A1 gene mutations cause vitreous degeneration and a high rate of complex retinal detachments.<sup>5,6</sup> Translational frameshift mutations are a common pathway by which disease is produced in patients with Stickler's syndrome.<sup>7</sup> The original family of the Wagner's syndrome (early onset cataracts, lattice degeneration of the retina, retinal detachment without involvement of nonocular tissues) is not linked to the COL2A1 gene and may be called Wagner's syndrome type I.

### OCULAR MANIFESTATIONS

High myopia (−8.00 to −18.00 diopters [D]) is the rule, as is an “optically empty” vitreous with abnormal membranes and strands. The optically empty vitreous refers to the presence of early onset, large lacunae of synergetic gel. It is best seen at the slit lamp through a widely dilated pupil. Dilated fundus examination typically reveals perivascular hyperpigmentary changes (Fig. 6.171). Retinal breaks are common and may lead to complicated retinal detachments (50% of eyes in patients with Stickler's syndrome). Giant retinal tears also may occur. Stickler's syndrome–associated retinal detachments are notoriously difficult to repair, due in part to the abnormal adherence between the vitreous and the retina.

Other ocular manifestations include presenile cataracts (in those patients less than 45 years of age, with peripheral, comma-shaped, cortical opacities). Open-angle glaucoma and ocular hypertension are additional problems found in patients with Stickler's syndrome.

### DIAGNOSIS AND ANCILLARY TESTING

Based on ocular findings alone, diagnostic precision can be difficult. Diagnostic criteria for Stickler's syndrome were published by the National Institutes of Health (NIH) in 2005, based on orofacial, ocular, auditory, and skeletal abnormalities with family history or molecular data (COL2A1 mutations).<sup>8</sup> Tests for the underlying gene defect are increasingly available to confirm a clinical diagnosis.

**Fig. 6.17.1 Fundus View of the Eye of a Patient With Stickler's Syndrome.** Note the radial perivascular pigmentary changes.

### BOX 6.17.1 Differential Diagnosis of Hereditary Vitreoretinopathies

#### Stickler's Syndrome

- Wagner's syndrome type I
- Erosive vitreoretinopathy<sup>9,10</sup>
- High myopia (degenerative type)
- Goldmann–Favre disease
- Retinitis pigmentosa

#### X-Linked Juvenile Retinoschisis

- Cystoid macular edema
- Rhegmatogenous retinal detachment
- Stargardt disease (atrophic macula)
- Goldmann–Favre disease
- Senile retinoschisis
- Retinitis pigmentosa

#### Autosomal Dominant Vitreoretinochoroidopathy

- Autosomal dominant neovascular inflammatory vitreoretinopathy<sup>11,12</sup>
- Retinitis pigmentosa
- Paving stone degeneration

#### Familial Exudative Vitreoretinopathy

- Retinopathy of prematurity
- Coats' disease
- Incontinentia pigmenti
- Sickle cell disease

#### Norrie's Disease

- Retinopathy of prematurity
- Persistent fetal vascular syndrome
- X-linked recessive familial exudative vitreoretinopathy

The electroretinography (ERG) changes are commensurate with axial myopia—reducing b-wave amplitudes. No intrinsic abnormality of the generators of the waveforms in the ERG appears to occur. Similarly, the perimetric abnormalities, if any, occur secondary to retinal detachments and do not result from abnormalities in the visual pathway directly. For the differential diagnosis of Stickler's syndrome, see [Box 6.17.1](#).

Differential diagnosis includes VCAN-related vitreoretinopathies of Wagner's syndrome (OMIM #143200) and erosive vitreoretinopathy (ERVR; OMIM \*118661). Versican (VCAN) is the only gene mutation associated with these two autosomal dominantly inherited diseases, characterized by “optically empty vitreous,” myopia, variable night blindness and chorioretinal atrophy, but no systemic associations.<sup>13</sup>

## SYSTEMIC ASSOCIATIONS

Of the diseases discussed in this chapter, both Stickler's syndrome and some autosomal dominant familial exudative vitreoretinopathy patients have systemic complications involving the skeleton. Generalized epiphyseal

dysplasia occurs, with premature degenerative changes in weight-bearing joints. Abnormalities of collagen that affect the head include submucous clefting of the palate and bifid uvula (75%; palpation with a gloved finger may be necessary to diagnose a submucous cleft). Midfacial flattening and the Pierre-Robin anomaly often are subtle, and radiographic studies may be required for diagnosis.<sup>14</sup> Sensorineural hearing loss often may be overlooked, as well as mitral valve prolapse (50%),<sup>15</sup> unless sought after in the systemic evaluation. The hearing loss is progressive and affects most individuals by middle age.

## TREATMENT, COURSE, AND OUTCOME

Early in life, corrective lenses based on a cycloplegic refraction are prescribed to prevent amblyopia. A multidisciplinary evaluation (otolar-yngology, orthopedics) and genetic tests (COL2A1 gene) with genetic counseling are important components of a global approach to the family with Stickler's syndrome. A good example of a growing phenomenon of self-organizing patient support groups is found in the United States at <http://www.sticklers.org/sip/> and in the United Kingdom at <http://www.stickler.org.uk/>. These groups serve multiple purposes, ranging from a source of scientific information to fundraising for research to find cures for the disease. Annual to semiannual retinal evaluation through dilated pupils with prophylactic treatment of new retinal tears is suggested for longitudinal follow-up. If retinal detachment does not occur, the visual morbidity is minimal. Low-vision evaluation may be beneficial for all patients who develop a serious loss of vision that affects activities of daily living.

## X-LINKED JUVENILE RETINOSCHISIS

### INTRODUCTION

X-linked juvenile retinoschisis (OMIM #312700) is a vitreoretinal degeneration affecting males. The cystic, spoke-like foveal changes, visual acuity deterioration, peripheral retinoschisis, and loss of ERG b-wave are bilateral. Despite mutation heterogeneity, there are relatively uniform clinical characteristics, albeit with intrafamilial variation in onset and severity.

### EPIDEMIOLOGY AND PATHOGENESIS

Various deleterious mutations in RS1 encoding for retinoschisin are associated with X-linked juvenile retinoschisis (XLRS; McKusick No. 312700). In a knockout mouse model, the RS1h murine analog seems important in organization of retinal cell layers and structure of the retinal synapse throughout the entire retina, in contrast to macular dominance in humans.<sup>16</sup>

Retinoschisin is a secreted, soluble homo-oligomeric complex that binds tightly to the surface of photoreceptors and bipolar cells to maintain the synapse. Wang et al. hypothesized that missense mutations lead to abnormal protein conformation and intracellular retention of these products.<sup>17</sup>

### OCULAR MANIFESTATIONS

Cystic-like, stellate maculopathy, or foveal schisis, is present almost universally in XLRS and may be the only abnormality detected by ophthalmoscopy in one-half of cases ([Fig. 6.17.2](#)). Similar to the findings in Goldmann–Favre disease, no late leakage occurs on fluorescein angiography. In older patients, foveal schisis evolves into an atrophic maculopathy. The average visual acuity is 20/60 (6/18) at age 20 years and 20/200 (6/60) at age 60 years.<sup>18</sup>

The classic histological studies of retinoschisis describe splitting in the anterior layers of the retina ([Fig. 6.17.3](#)), typically in the inferotemporal quadrant, and bilaterally in 40% of patients. The inner layer balloons into the vitreous cavity, and unsupported retinal vessels may lead to recurrent vitreous hemorrhages from associated vitreous traction. Vitreous veils may overlie the retinoschisis.<sup>19</sup> In XLRS, the vitreous exerts an effect on the bullous nature of the retinoschisis lesion. The elevation is seen to flatten after a posterior vitreous detachment has produced a separation between the vitreous face and the internal limiting membrane. It is as if the vitreous releases the inner layers of the retina, which allows them to settle back into an anatomical position.

The Mizuo–Nakamura phenomenon has been described in four unrelated men who suffered from X-linked recessive retinoschisis.<sup>20</sup> Originally described in patients who had autosomal recessive Oguchi's disease, a form

**Fig. 6.17.2 Fundus View of Foveal Schisis Seen in a Man Who Has X-Linked Juvenile Retinoschisis.** This lesion should not be confused with cystoid macular edema.

#### BOX 6.17.2 Diseases With Selective Loss of B-Wave Amplitude on Electroretinographic Testing

- X-linked juvenile retinoschisis
- Congenital stationary night blindness
- Oguchi's disease
- Myotonic dystrophy
- Batten's disease (neuronal ceroid lipofuscinosis)
- Autosomal dominant neovascular inflammatory vitreoretinopathy
- Quinine toxicity
- Methanol toxicity
- Siderosis
- Acute central retinal artery occlusion
- Acute central retinal vein occlusion

of congenital stationary night blindness, this phenomenon also occurs in patients who have an X-linked cone dystrophy.<sup>21</sup>

### DIAGNOSIS AND ANCILLARY TESTING

The diagnosis is largely based on clinical examination. In contrast to the histological studies showing anterior layer splitting, spectral domain optical coherence tomography (OCT) shows widespread cystic spaces in both inner and outer macular retina. OCT also reveals subtle structural changes throughout different layers of the retina that vary between the fovea and parafovea. OCT may ultimately improve our understanding of retinoschisis by nondestructively showing disease progression over time and the variation in the depth of retinal splitting by eccentricity from fovea to the periphery. Fluorescein angiography generally shows no leakage of dye or true cystoid macular edema in the posterior pole, whereas the periphery may show slow filling of opacified, dendritic retinal vessels.<sup>22</sup>

The ERG shows selective loss of the b-wave amplitude for the scotopic, nonattenuated flash and loss of the oscillatory potentials (Box 6.17.2). This ERG abnormality suggests a panretinal dysfunction in spite of the ophthalmoscopic appearance of only foveal retinal schisis. No consistent ERG findings are found in female carriers, although sporadic reports of abnormalities exist.

Visual fields demonstrate absolute scotomas in areas of peripheral schisis, because the neural chain of information is interrupted. A relative central scotoma also is seen. Dark adaptation is normal or only minimally affected in X-linked retinoschisis. There are no known systemic associations. For the differential diagnosis of XLRS, see Box 6.17.1.

### TREATMENT, COURSE, AND OUTCOME

Prophylactic treatment of retinoschisis or holes in schisis is not recommended, whereas secondary retinal detachment necessitates intervention. Combined retinal detachment and retinoschisis requires intervention to

**Fig. 6.17.3 Juvenile Retinoschisis.** (A) The characteristic foveal lesion, resembling a polycystic fovea, is shown. Typically, no leakage is present when fluorescein angiography is performed. (Courtesy Dr. A. J. Brocker.) (B) A histological section of another eye shows a large temporal peripheral retinoschisis cavity. (C) A histological section of another area of the same eye shows a splitting in the ganglion and nerve fiber layers of the retina on the earliest finding in juvenile retinoschisis. This pathology of the inner retinal layers is the same as that seen in reticular microcystoid degeneration and retinoschisis. (B–C Courtesy Dr. M. Yanoff.)

close the outer layer holes and full-thickness retinal breaks by vitrectomy, perfluorocarbon reattachment, and panretinal photocoagulation to areas of schisis and detachment, with scleral buckling of the retinal periphery. In young patients who are unable to comply with rigorous postoperative positioning requirements imposed by instillation of long-acting gas, silicone oil tamponade may be preferable.

Genetic counseling is necessary in all cases. Carrier state detection by clinical exam alone is difficult in this disease, although isolated reports exist. Most patients develop a significant loss of macular function in one or both eyes with time. Children need to be examined frequently to rule out amblyopia, vitreous hemorrhage, or retinal detachment.

The National Eye Institute's Study NCT02317887 is a phase 1/2 gene therapy trial in humans using AAV8-scRS/IRBPhRS injected intravitreally. Applied Genetic Technologies is also conducting a human gene therapy trial using rAAV2tYF-CB-hRS1 injected intravitreally.

## AUTOSOMAL DOMINANT VITREORETINOCHOROIDOPATHY

### EPIDEMIOLOGY AND PATHOGENESIS

Mutations in the BEST1 gene cause a range of clinically heterogeneous retinal dystrophies, collectively called bestrophinopathies. These include Best disease (OMIM #153700), adult-onset vitelliform macular dystrophy (OMIM #608161), autosomal recessive bestrophinopathy (OMIM #611809), retinitis pigmentosa (OMIM #26800 and #613194), and ADVIRC (OMIM #193220).<sup>23</sup>

### OCULAR MANIFESTATIONS

The classic finding of ADVIRC is a sharply defined posterior border to an area of abnormal hypopigmentation or hyperpigmentation for 360° bilaterally between the ora serrata and the equator (Fig. 6.174).<sup>24,25</sup> Within this abnormally pigmented area are narrowed retinal arterioles, vascular incompetence, retinal neovascularization, punctate white retinal opacities, and later retinochoroidal atrophy. Cystoid macular edema, if present, is the most significant morbidity, although central retinal pigment epithelial atrophy can be seen in elderly patients. Vitreous hemorrhage and epiretinal membranes also may affect the visual acuity. Profound alterations in the vitreous body are not described, although small numbers of vitreous cells and early posterior vitreous detachments may occur. The condition is slowly progressive and is not associated with retinal detachments. Histopathology has been described in an 88-year-old patient; similar features to retinitis pigmentosa were found, along with some differences.<sup>26</sup>

**Fig. 6.17.4 Fundus View of Retinal Periphery in Autosomal Dominant Vitreoretinopathy.** Note sharply demarcated posterior border to the hyperpigmented peripheral lesion. This border is a useful defining feature of autosomal dominant vitreoretinopathy.

## DIAGNOSIS AND ANCILLARY TESTING

Patients who have ADVIRC generally have no nyctalopia, and ERG findings are normal in younger affected individuals and only moderately depressed in older patients. No known systemic associations exist. For the differential diagnosis of ADVIRC, see Box 6.17.2.

### TREATMENT, COURSE, AND OUTCOME

Annual or biannual dilated fundus examination is suggested unless the disease is symptomatic. Cystoid macular edema typically responds to dorzolamide. The long-term visual prognosis is generally good, though late stage ADVIRC may produce macular RPE atrophy and decreased vision.

## FAMILIAL EXUDATIVE VITREORETINOPATHY

### INTRODUCTION

FEVR, reported initially in 1969 by Criswick and Schepens,<sup>27</sup> has also been called dominant exudative vitreoretinopathy. Both eyes are affected but usually asymmetrically.

### EPIDEMIOLOGY AND PATHOGENESIS

Three genes are associated with autosomal dominantly inherited FEVR (OMIM #133780): FZDD4, encodes the frizzled-4 protein; LRP5, encodes low-density lipoprotein receptor-related protein 5; and TSPAN12, encoding tetraspanin-12.

The frizzled-4 protein is a member of the frizzled family of seven-pass transmembrane receptors that bind Wnt proteins.<sup>28</sup> The norrin gene product acts as ligand for the FZD-4 protein receptor, which in turn activates the Wnt signaling pathway.<sup>29</sup> Among many critical developmental pathways that Wnt affects, it is involved in the blood supply to the retina and inner ear. The LRP5 encodes a single-pass transmembrane receptor, partnering with frizzled-4 to bind Wnt proteins. TSPAN12 encodes a four-pass transmembrane protein, forming a component of the norrin-LRP5-FZD-4 signaling complex. Mutations in these three genes account for less than 50% of adFEVR. Genetic testing is increasingly available with certified genetics counselors knowledgeable of the genetic testing labs. Genetic heterogeneity in FEVR is documented.<sup>30,31</sup> Although rare, FEVR accounts for a significant percentage of all retinal detachments in juvenile and infant patients.

### OCULAR MANIFESTATIONS

The prominent feature is the abrupt cessation of peripheral retinal vessels in a scalloped pattern at the temporal equator (Figs. 6.17.5 and 6.17.6). Dilated retinal vessels may result in peripheral neovascularization with adjacent preretinal hemorrhage and may later evolve into a fibrovascular

**Fig. 6.17.5 Fundus View of a Patient Who Has Familial Exudative Vitreoretinopathy.** Note abnormally straightened retinal vasculature.

scar.<sup>32</sup> Subretinal exudates occur in 10%–15% of eyes and can become massive, resembling Coats' disease.

The majority of retinal detachments occur in the first decade of life, with little progression after 10 years of age.<sup>33,34</sup> Vitreous abnormalities include posterior vitreous detachment and vitreous bands or sheets attached to avascular retina, although milder cases may not show any visible vitreous change. An ectopic macula may be found in 50% of patients. A positive-angle kappa or strabismus is common.

## DIAGNOSIS AND ANCILLARY TESTING

The diagnosis is based on typical clinical findings, a positive family history, the lack of significant prematurity, and the exclusion of other possible causes of peripheral retinal pathology. Fluorescein angiography can be quite helpful because it highlights peripheral, nonperfused retina and shows the characteristic straightening of peripheral retinal vessels.

No significant ERG findings are noted. Even patients who have enough avascular peripheral retina to produce peripheral retinal neovascularization show only minor reductions in b-wave amplitude. No known systemic associations occur. For the differential diagnosis of FEVR, see [Box 6.172](#).

## SYSTEMIC ASSOCIATIONS

Toomes et al. observed osteopenia or osteoporosis on dual X-ray absorptiometry in patients with autosomal dominant FEVR and mutations in *LRP5*.<sup>35</sup> It should be remembered that in Stickler's syndrome, patients with mutations in procollagen II have ocular and skeletal problems as well.

Interestingly, missense mutations within the first few exons of *LRP5* are associated with disorders of high bone mass: high bone mass (OMIM 601884), endosteal hyperostosis (OMIM 144750), and osteopetrosis (OMIM 607634).<sup>36</sup>

**Fig. 6.17.6 Fluorescein Angiogram of a Patient Who Has Familial Exudative Vitreoretinopathy.** Fluorescein angiography is an excellent tool to define the abnormal retinal vasculature in familial exudative vitreoretinopathy. Fluorescein angiography, if available, is particularly useful for peripheral retinal vascular examination.

## TREATMENT, COURSE, AND OUTCOME

Early screening of at-risk individuals is useful to identify nonperfused peripheral retina. Wide-field fluorescein angiography can identify large areas of avascular peripheral retina.

Strabismus from dragged retina must be identified early. Retinal detachments primarily are tractional early in life and combined tractional and rhegmatogenous in the second decade (4%–30% incidence).

## NORRIE'S DISEASE

### INTRODUCTION

Norrie's disease (ND; OMIM #310600) is a rare, bilateral, blinding X-linked recessive disorder, with 30%–50% of patients developing sensorineural deafness and mental retardation.

### EPIDEMIOLOGY AND PATHOGENESIS

The ND gene (NDP \*300658) on chromosome Xp11.4 produces the gene product norrin, a small secreted protein with a cysteine-knot motif. The cysteine-knot motif is highly conserved in many growth factors, such as transforming growth factor beta, human chorionic gonadotropin, nerve growth factor, and platelet-derived growth factor. Norrin acts as a ligand in a Wnt receptor-beta catenin signal transduction pathway that plays a regulatory role in retinal vascular development. FZD-4 gene receptors and LRP-5 gene receptors (see FEVR) are coupled to the beta catenin canonical pathway activating Wnt target genes.<sup>37</sup>

### OCULAR MANIFESTATIONS

The congenitally dysplastic retina presents as a grayish yellow mass known as a pseudoglioma. Partial or complete retinal detachment evolves over the first few months, with typically light perception vision at best.<sup>38</sup>

At birth the anterior segment may be normal, with the pseudoglioma appearance visible behind a clear lens. However, progressive cataract, posterior synechiae, as well as shallowing of the anterior chamber and anterior synechiae may follow. Angle-closure glaucoma and a painful eye may develop, followed by band keratopathy hypotony and phthisis bulbi ([Fig. 6.177](#)).

### DIAGNOSIS AND ANCILLARY TESTING

A clinical diagnosis of ND requires the presence of bilateral dystrophic retinas. Increasingly, genetic diagnostic precision is desirable. Prenatal testing is possible for female carriers if the NDP mutation has been identified in a family member. Chorionic villous sampling may be performed at 10–12 weeks' gestation or by amniocentesis at 15–18 weeks' gestation.

Persistent fetal vasculature syndrome (PFVS) is diagnosed in children with findings suggestive of ND but lacking an X-linked recessive inheritance or an ND gene mutation.

### SYSTEMIC ASSOCIATIONS

Sensorineural deafness and mental retardation are present in 30%–50% of patients.

**Fig. 6.17.7 Color Fundus Photograph of Norrie's Disease Patient Showing Profound Retinal Disorganization Arising From Disordered Development (Pseudoglioma).** 'Pumpkin lesion' comprised of vascularized dysplastic retinal mass (pseudoglioma) in posterior pole. (Courtesy Dr. K. A. Drenser.)

## TREATMENT, COURSE, AND OUTCOME

Walsh et al. describe 14 boys with ND who underwent vitrectomy with or without lensectomy prior to 12 months of age. Seven maintained at least light perception in at least one eye, and three had no light perception bilaterally.<sup>39</sup>

A family history and genetic counseling may lead to a high index of suspicion of ND, leading to careful consideration of prenatal amniocentesis fetal-genetic testing. Chow et al. describe a case of induced labor at 37 weeks' gestation, confirmatory examination under anesthesia at 1 day after birth, and bilateral application of laser to avascular retina via binocular indirect ophthalmoscopic delivery. Extraretinal neovascularization regressed fully at one month without retinal detachment. At 23 months, Teller visual acuity was 20/100 OU.<sup>40</sup>

Surveillance for and treatment of hearing loss may include hearing aids and consideration of cochlear implants.

# Hypertensive Retinopathy

Aleksandra V. Rachitskaya

# 6.18

## CHRONIC HYPERTENSIVE RETINOPATHY

**Definition:** Retinal vascular changes occurring from chronic systemic arterial hypertension.

### Key Features

- Arteriolar narrowing.
- Arteriovenous nicking.
- Microaneurysms.
- Silver/copper wiring.

### Associated Retinal Findings

- Branch retinal vein occlusion.
- Central retinal vein occlusion.
- Macroaneurysm.

## MALIGNANT ACUTE HYPERTENSIVE RETINOPATHY

**Definition:** Retinal, choroidal, and optic nerve changes secondary to acutely elevated systemic arterial blood pressure.

### Key Features

- Retinal hemorrhages.
- Cotton-wool spots.
- Serous retinal detachment.
- Optic disc edema.
- Choroidal ischemia.

### Associated Feature

- Malignant hypertension, encephalopathy, pre-eclampsia, eclampsia, kidney disease, and pheochromocytoma.

## INTRODUCTION

Hypertensive retinopathy represents ophthalmic findings secondary to systemic elevated blood pressure. Retinal as well as choroidal and optic nerve circulations can be affected. Both chronic structural damage and acute changes due to rapid elevation of blood pressure can be observed. Chronic changes include arteriolar narrowing, arteriovenous nicking, and copper and silver wiring. Microaneurysms, retinal blot and flame-shaped hemorrhages, hard exudates, and cotton-wool spots commonly are associated with exudative retinopathy. Acute changes associated with episodes of rapidly elevated blood pressure can include disc edema, choroidal infarction, along with exudative retinopathy.

Hypertensive retinopathy and hypertension are associated with development and progression of such vision-threatening disorders as retinal vein and artery occlusion, macroaneurysms, and diabetic retinopathy. Retinopathy is also an independent risk factor for stroke, cardiovascular

mortality, renal disease, and cognitive decline. Given the high prevalence of hypertension, its association with cardiovascular complications and end organ damage, and poor blood pressure control among particular groups of patients, ophthalmologists play a role in establishing a diagnosis and educating patients about potential ramifications.

## EPIDEMIOLOGY AND PATHOGENESIS

Hypertension (HTN) is defined as systolic blood pressure greater than or equal to 140 mm Hg or diastolic blood pressure greater than or equal to 90 mm Hg.<sup>1</sup> Essential HTN, not secondary to another disease process, is most common. Prevalence of HTN among US adults was 29% in 2011–2014; it increases with age and was found in 65% of those age 60 years and older. HTN prevalence is highest among non-Hispanic African Americans,<sup>1</sup> and affects approximately 1 billion adults worldwide.<sup>2</sup> Systolic blood pressure represents an independent risk predictor for coronary events, stroke, heart failure, and end-stage renal disease.<sup>3</sup> However, among adults with HTN, only 53% had controlled blood pressure during 2011–2014, and young adults aged 18–39 tend to have lower awareness, treatment, and control (37%) of their HTN.<sup>1</sup>

The hypertensive retinal changes are often associated with and masked by the presence of other retinal vascular diseases such as diabetes and vein occlusion. The prevalence of retinopathy has been reported to range from 6.6% to 17.2% and varies with race and ethnicity.<sup>4–7</sup> Retinopathy without diabetes could also be related to increasing age, hyperglycemia, dyslipidemia, higher body mass index, and systemic inflammatory markers.<sup>6</sup> It has, however, been shown that HTN is the major cause of retinopathy without diabetes.<sup>4,8</sup>

HTN itself is a risk factor for development and progression of diabetic retinopathy, retinal vein and artery occlusion, retinal–arteriolar emboli, nonarteritic ischemic optic neuropathy, and retinal arterial macroaneurysm.<sup>9,10</sup> It has also been reported to be a risk factor for age-related macular degeneration and glaucoma.<sup>9–11</sup> Moreover, after risk factors such as systolic blood pressure and diabetes are controlled, advanced retinopathy is independently associated with clinical and subclinical stroke and cardiovascular mortality, congestive heart failure, renal disease, and cognitive decline and dementia.<sup>12–18</sup> The relationship of hypertensive retinopathy with cerebrovascular disease is the strongest.<sup>19</sup>

## OCULAR MANIFESTATIONS

### Hypertensive Retinopathy

The pathophysiology of hypertensive retinopathy is believed to occur in overlapping and not always sequential phases: a vasoconstrictive phase, an exudative phase, a sclerotic phase, and complications of the sclerotic phase.<sup>20</sup> The arterioles and capillaries are affected.

In the early vasoconstrictive phase, a rise in systemic blood pressure excites pliable and nonsclerotic retinal vessels to increase their vascular tone. It usually presents as generalized retinal arteriolar narrowing.<sup>19–21</sup> Persistently elevated blood pressure leads to intimal thickening, hyperplasia of the media wall, and hyaline degeneration. In this sclerotic stage, there are areas of severe generalized and focal arteriolar narrowing. Arteriovenous nicking occurs due to arteriolar compression of venules at their junctions as they share a common adventitial sheath (Fig. 6.18.1). Alterations in the arteriolar light reflex are described as copper and silver wiring.<sup>21</sup> The complications of the sclerotic phase include formation of macro- and microaneurysms of the retinal artery, artery or vein occlusion, and epiretinal membrane formation (Fig. 6.18.2).<sup>20</sup>

In the exudative phase, which is usually associated with an acute rise in blood pressure, the blood–retinal barrier is disrupted, resulting in

**Fig. 6.18.1 Mild to Moderate Chronic Hypertensive Retinopathy.** Note the nerve fiber layer hemorrhage and sporadic areas of arteriovenous nicking. Blood pressure measured 168/93.

**Fig. 6.18.2 Collateral Vessels in the Superior Macula of a Patient With Hypertensive Retinopathy and a Resolved Branch Retinal Vein Occlusion.** A few microaneurysms and retinal hemorrhages persist from the occlusion.

exudation of blood and lipids and retinal ischemia. Clinically, microaneurysms, focal intraretinal periarteriolar transudates, retinal blot (inner retinal) and flame-shaped (nerve fiber layer) hemorrhages, hard exudates, and cotton-wool spots are seen (Fig. 6.18.3). Cotton-wool spots represent focal ischemic areas of the nerve fiber layer. In cases of acute blood pressure elevation, the swelling of the optic disc and choroidal ischemia may occur as described later.<sup>20-22</sup>

Generalized arteriolar narrowing and arteriovenous nicking is usually seen in chronic hypertensive damage and might correspond to historic and not to current blood pressure levels. On the other hand, focal arteriolar narrowing, retinal hemorrhages, microaneurysms, and cotton-wool spots are associated with concurrently measured blood pressure.<sup>9</sup>

There have been several classification systems of hypertensive retinopathy (Box 6.18.1).<sup>10,23</sup> These have not been extensively utilized, as interobserver variability has been reported. Suggestions have been made to establish a photographic classification of the retinal signs similar to diabetic retinopathy.<sup>18</sup>

For differential diagnosis of hypertension retinopathy, see Box 6.18.2.

## Hypertensive Choroidopathy

Hypertensive choroidopathy usually occurs in association with acutely elevated blood pressure and more frequently affects younger patients whose blood vessels are pliable and not sclerotic.<sup>20</sup> Hypertensive emergencies are

**Fig. 6.18.3 Moderate Hypertensive Retinopathy.** Microaneurysms, retinal blot and flame-shaped hemorrhages, arteriovenous nicking, and cotton-wool spots.

### BOX 6.18.1 Classifications of Hypertensive Retinopathy

#### Keith-Wagener-Barker Classification

- Grade 1: Generalized arteriolar narrowing
- Grade 2: Focal narrowing and arteriovenous nicking/nipping
- Grade 3: Grade 2 plus exudates, hemorrhages, and cotton-wool spots
- Grade 4: Grade 3 plus optic disc swelling

#### Mitchell-Wong Classification

- Mild: generalized and/or focal arteriolar narrowing, arteriovenous nicking/nipping, opacity of arteriolar wall (copper/silver wiring)
- Moderate: retinal hemorrhages (flame, dot, blot), exudates, cotton-wool spots
- Malignant: moderate plus optic disc swelling

### BOX 6.18.2 Differential Diagnosis of Chronic Hypertensive Retinopathy

- Diabetic retinopathy
- Retinal venous obstruction
- Hyperviscosity syndromes
- Congenital hereditary retinal arterial tortuosity
- Ocular ischemic syndrome
- Radiation retinopathy

characterized by severe elevations in blood pressure above 180/120 mm Hg.<sup>24</sup> Malignant hypertension and encephalopathy might be present. It can be seen in patients with pre-eclampsia, eclampsia, essential hypertension, kidney disease, and pheochromocytoma.<sup>20</sup> The retinal changes, as described above, include focal intraretinal periarteriolar transudates, microaneurysms, retinal flame-shaped hemorrhages, hard exudates, and cotton-wool spots. Optic nerve swelling can be present as well. Choroidal changes involve patchy perfusion of choriocapillaris. Histologically, it is due to fibrinoid necrosis of the choroidal arteries and arterioles with occlusion of the choriocapillaris.<sup>20</sup> Areas of focal choroidal ischemia called Elschnig's spots appear as pale, yellow, well-demarcated lesions that with time become pigmented as a secondary consequence of tissue infarction (Fig. 6.18.4).<sup>10</sup> Global choroidal dysfunction affects the pumping capacity of the retinal pigment epithelium, leading to exudative retinal detachments that are usually posterior in location (Fig. 6.18.5). Siegrist's streaks are the rarest finding and present as linear configurations of hyperpigmentation that develop over choroidal arteries. The pigmentation has been attributed to hypertrophy and hyperplasia of the retinal pigment epithelium. The streaks usually radiate out to the periphery, passing deep to the retinal vessels along the course of sclerosed choroidal vessels.<sup>25</sup>

**Fig. 6.18.4** Elschnig's Spots.

**Fig. 6.18.5** Serous Detachment of the Retina in a 27-Year-Old Patient Who Has Pregnancy-Induced Hypertension, 3 Days Postpartum. Blood pressure measured 158/100 mm Hg. Note the subretinal fibrin and folds in the retina. (Courtesy Franklin L. Myers.)

## Hypertensive Optic Disc Edema

Optic nerve edema is usually seen in acutely elevated blood pressure. Raised intracranial pressure and concomitant optic nerve ischemia have been implicated to lead to disc swelling (Fig. 6.18.6).<sup>20,26</sup> Subsequent optic nerve pallor can occur. Acute and significant lowering of the blood pressure can result in optic nerve head infarction and subsequent marked optic atrophy and permanent vision loss.<sup>26</sup>

For differential diagnosis of acute hypertension retinopathy, see Box 6.18.3.

## DIAGNOSIS AND ANCILLARY TESTING

Hypertensive retinopathy is a clinical diagnosis made when characteristic retinal vascular, choroidal, or optic disc changes are visualized on slit-lamp biomicroscopy. Ancillary studies can help confirm the diagnosis. Fluorescein angiography (FA) demonstrates narrowing of the retinal arteries, arterioles, and capillary bed, which is the earliest angiographic feature of systemic hypertension. Multiple focal areas of severe retinal ischemia secondary to focal arteriolar narrowing or occlusion are seen. Dilated retinal capillaries and microaneurysms develop at the margins of these areas, which are typically located around the optic disc or along the major retinal vessels (Fig. 6.18.7).<sup>27</sup> In malignant HTN, the optic nerve hyperfluorescence and leakage are seen.<sup>28</sup>

Cotton-wool spots are due to ischemia of the nerve fiber layer. On optical coherence tomography (OCT), they are seen as hyperreflectivity of the nerve fiber layer that subsequently results in permanent damage and thinning.<sup>29,30</sup>

FA and OCT are also useful in conditions associated with HTN and hypertensive retinopathy such as macroaneurysms, retinal artery or vein occlusion, and diabetic retinopathy.

**Fig. 6.18.6** Bilateral Malignant Hypertensive Retinopathy in a Patient With Blood Pressure of 260/140. (A) Right and (B) left eyes. Disc edema, exudate, retinal hemorrhages, venous dilation, narrowing of the arterioles, Elschnig's spots, and Siegrist's streaks are all present. (Courtesy Thomas Hedges III, MD.)

### BOX 6.18.3 Differential Diagnosis of Acute Hypertensive Retinopathy

- Bilateral central serous chorioretinopathy
- Bilateral central retinal vein obstruction
- Collagen vascular diseases
- Diabetic retinopathy (especially in the setting of diabetic papillopathy)

## TREATMENT AND FUTURE DIRECTIONS

The US Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VII), the Canadian Hypertension Education Program, and the World Health Organization (WHO) International Society of Hypertension identify hypertensive retinopathy as target organ damage.<sup>24,31,32</sup> Documented target organ damage can affect patients' treatment and follow-up schedule. The British Hypertension Society 2004 Guidelines (BHS IV) indicated that severe HTN and grade III–IV retinopathy are suggested indications for specialist referral.<sup>33</sup>

**Fig. 6.18.7** The Right Eye of the Same Patient as Shown in Fig. 6.18.3. (A) A prominent cotton-wool spot in the papillomacular bundle is seen with an adjacent intraretinal hemorrhage. (B) Fluorescein angiography shows capillary nonperfusion in the area corresponding to the cotton-wool patch; note the hypofluorescence of the intraretinal hemorrhage, caused by blockage.

Advanced hypertensive retinopathy is also a risk factor for subclinical and clinical stroke, cognitive decline, and cardiovascular mortality.<sup>12–18</sup>

One of the challenges in hypertensive retinopathy research is a lack of a single classification scheme.<sup>18</sup> Hypertensive changes are often seen in patients with diabetes and arteriosclerotic vascular disease. In the past, it has also been noted that the assessment of retinal microvascular changes varied between observers.<sup>34</sup> Recent advances in digital retinal imaging provide an opportunity to quantify and monitor hypertensive retinopathy, including such imaging biomarkers as retinal vessel width.<sup>19,35</sup> These objective findings could also be utilized in the emerging world of telemedicine.<sup>36</sup>

The newer imaging modalities of wide-field imaging, adaptive optics, and OCT angiography might contribute to our understanding of hypertensive retinopathy. For instance, adaptive optics are used to describe the shapes of microaneurysms and to quantitatively examine the retinal vasculature.<sup>37,38</sup> Study of retinal vessel caliber provides a noninvasive approach that could allow evaluation of systemic microvascular morphology.<sup>39–41</sup>

# Retinal Arterial Obstruction

Jacob S. Duker, Jay S. Duker

# 6.19

## CENTRAL RETINAL ARTERY OBSTRUCTION

**Definition:** An abrupt diminution of blood flow through the central retinal artery severe enough to cause ischemia of the inner retina.

### Key Features

- Abrupt, painless, severe loss of vision.
- Cherry-red spot.
- Box-carring of blood flow in the retinal vessels.
- Ischemic retinal whitening of the posterior pole.

### Associated Features

- Amaurosis fugax.
- Visible embolus (25%).
- Carotid artery stenosis (33%).
- Giant cell arteritis (5%).
- Neovascularization of the iris (18%).
- Arterial collaterals on the optic disc.

## BRANCH RETINAL ARTERY OBSTRUCTION

**Definition:** An abrupt diminution of blood flow through a branch of the central retinal artery severe enough to cause ischemia of the inner retina in the territory of the affected vessel.

### Key Features

- Retinal whitening in the territory of the obstructed vessel.
- Visible embolus (66%).
- Visual field defect that corresponds to the territory of the obstructed vessels.

### Associated Features

- Carotid artery disease.
- Cardiac valvular disease.
- Cardiac myxoma, long-bone fracture, endocarditis, depot drug injection (rare).
- Systemic clotting disorder or vasculitis (rare).

## CENTRAL RETINAL ARTERY OBSTRUCTION

### INTRODUCTION

Retinal arterial obstructions are divided anatomically into central and branch, depending on the precise site of obstruction. A central retinal artery obstruction occurs when the blockage is within the optic nerve substance itself, and therefore the site of obstruction is generally not visible on ophthalmoscopy. A branch retinal artery obstruction occurs when the site of blockage is distal to the lamina cribrosa of the optic nerve.

Obstructions more proximal to the central retinal artery, in the ophthalmic artery, or even in the internal carotid artery may produce visual loss

as well. Ophthalmic artery obstructions may be difficult to differentiate from central retinal artery obstruction. More proximal obstructions usually cause a more chronic form of visual problem—the ocular ischemic syndrome (see Chapter 6.23).

The majority of retinal arterial obstructions are either thrombotic or embolic in nature. The potential sources and various types of emboli generally do not differ between central retinal artery obstruction and branch retinal artery obstruction, but a branch retinal artery obstruction is far more likely to be embolic than is a central retinal artery obstruction. It has been determined that over two-thirds of branch retinal artery obstructions are caused by emboli, whereas probably less than one-third of central retinal artery obstructions result from emboli.

The retina has a dual circulation with little to no anastomoses. The inner retina is supplied by the central retinal artery, which is an end artery. The outer retina receives its nourishment via diffusion from the choroidal circulation (see Chapter 6.3). Retinal artery obstructions selectively affect the inner retina only.

Because the accompanying visual loss tends to be severe and permanent, it is fortunate that retinal artery obstructions are rare occurrences. As there is a strong association with systemic disease, all patients who suffer retinal artery obstructions should undergo a systemic evaluation.

## EPIDEMIOLOGY AND PATHOGENESIS

Central retinal artery obstruction is a rare event—it has been estimated to account for about 1 in 10 000 outpatient visits to the ophthalmologist.<sup>1</sup> The incidence was found to be 1.3 per 100 000, or 1.90 per 100 000 when adjusted for age and sex for the white population in the United States.<sup>2</sup> Men are affected more commonly than women, in a ratio of 2:1. The mean age at onset is about 60 years, with a range of reported ages from the first to the ninth decade of life. Right eyes and left eyes appear affected with equal incidence. Bilateral involvement occurs in 1%–2% of cases.

In central retinal artery obstruction, the site of obstruction is not usually visible on clinical examination and, in general, the retrobulbar central retinal artery is too small to image with most techniques. Therefore, the precise cause is speculative. It is currently believed that the majority of central retinal artery obstructions are caused by thrombus formation at or just proximal to the lamina cribrosa. Atherosclerosis is implicated as the inciting event in most cases, although congenital anomalies of the central retinal artery, systemic coagulopathies, or low-flow states from more proximal arterial disease may also be present and render certain individuals more susceptible.

In only 20%–25% of cases are emboli visible in the central retinal artery or one of its branches, suggesting that an embolic cause is not frequent. A more detailed discussion of embolus types is given later in the section on branch retinal artery obstruction. Further indirect evidence against emboli as a frequent cause of central retinal artery obstruction is the 40% or less probability of finding a definitive embolic source on systemic evaluation and the small incidence (approximately 10%) of confirmed associated ipsilateral cerebral emboli in affected patients.<sup>3</sup>

Inflammation in the form of vasculitis (e.g., varicella infection), optic neuritis, or even orbital disease (e.g., mucormycosis) may cause central retinal artery obstruction.<sup>4,5</sup> Local trauma that results in direct damage to the optic nerve or blood vessels may lead to central retinal artery obstruction.<sup>6</sup> Arterial spasm or dissection rarely produces retinal arterial obstruction. In addition, systemic coagulopathies may be associated with both central and branch retinal artery obstructions.<sup>7</sup>

Other rare causes include radiation retinopathy,<sup>8</sup> emboli associated with depot medication injection around the eye,<sup>9</sup> cosmetic facial injection with filler materials,<sup>10</sup> optic disc drusen, and prepapillary arterial loops. Medical examinations and manipulations (e.g., carotid angiography, angioplasty,

**Fig. 6.19.1 The Left Eye of a Healthy 37-Year-Old Man.** The patient had a 3-hour history of visual loss and a visual acuity of 20/60 (6/18). (A) Retinal whitening is very subtle and the retinal vessels appear normal. (B) Fluorescein angiography reveals abnormal arterial filling with a leading edge of dye that confirms central retinal artery obstruction. (C) The same eye 24 hours later. Despite intravenous urokinase, visual acuity dropped to hand movements, and intense retinal whitening with a cherry-red spot is present. Note the interruption in the blood column of the retinal arteries.

### BOX 6.19.1 Other Causes of a Cherry-Red Spot

- Tay–Sachs disease
- Farber’s disease
- Sandhoff’s disease
- Niemann–Pick disease
- Goldberg’s syndrome
- Gaucher’s disease
- Ganglioside GMI, type 2
- Hurler’s syndrome (mucopolysaccharidosis 1 H)
- $\beta$ -Galactosidase deficiency (mucopolysaccharidosis VII)
- Hallevorden–Spatz disease
- Batten–Mayou–Vogt–Spielmeyer disease

chiropractic neck manipulation) rarely result in emboli to the central retinal artery.<sup>11,12</sup> Although elevated intraocular pressure has been implicated as a cause of central retinal artery obstruction, it is unlikely that intraocular pressure can be raised high enough to block arterial inflow to the eye.

## OCULAR MANIFESTATIONS

The hallmark symptom of acute central retinal artery obstruction is abrupt, painless loss of vision.<sup>13</sup> Pain is unusual and suggests associated ocular ischemic syndrome (OIS). Amaurosis fugax precedes visual loss in about 10% of patients. Rarely, in cases associated with arterial spasm, a relapsing and remitting course of visual loss precedes central retinal artery obstruction.<sup>14</sup>

Examination typically reveals a visual acuity of 20/800 (6/240) or worse.<sup>15</sup> Hand motion or light perception vision can occur, but no light perception vision is uncommon except in the setting of an ophthalmic artery obstruction or temporal arteritis. If a patent cilioretinal artery is present and perfuses the fovea, normal central acuity may be present. An afferent pupillary defect on the affected side is the rule. Anterior segment examination is normal except in the setting of concurrent OIS with neovascularization of the iris.

Within the first few minutes to hours after the obstruction, the fundus may appear relatively normal (Fig. 6.19.1A–B). Eventually, the decreased blood flow results in ischemic whitening of the retina in the territory of the obstructed artery, which is most pronounced in the posterior pole (where the nerve fiber layer of the retina is thickest). Acutely, the arteries appear thin and attenuated. In severe blockages, both veins and arteries may manifest “box-carring” or segmentation of the blood flow.

A cherry-red spot of the macula is typical and arises in this area because the nerve fiber layer is thin. Transmission of the normal choroidal appearance, therefore, is not diminished, which contrasts distinctly with the surrounding area of intense retinal whitening that blocks transmission of the normal choroidal coloration. Although other conditions may be associated with a macular cherry-red spot (Box 6.19.1), these are usually differentiated easily from central retinal artery obstruction. Splinter retinal hemorrhages on the disc are common, but more extensive retinal hemorrhaging suggests an alternative diagnosis. If pallid swelling is present, temporal

**Fig. 6.19.2 A Central Retinal Artery Obstruction.** A prominent cherry-red spot with cilioretinal artery sparing in the papillomacular bundle.

arteritis must be ruled out. A patent cilioretinal artery results in a small area of retina that appears normal (Fig. 6.19.2).

By 6 weeks after the acute event, the retinal whitening typically resolves, the optic disc develops pallor, and arterial collaterals may form on the optic disc. No foveolar light reflex is apparent, and fine changes in the retinal pigment epithelium may be visible. Secondary ocular neovascularization is not uncommon after central retinal artery obstruction and tends to occur around 8 weeks after the obstruction (range 2–16).<sup>16</sup> Iris neovascularization occurs in about 18% of patients,<sup>17,18</sup> with many of these eyes going on to neovascular glaucoma. Panretinal photocoagulation appears to reduce the risk of neovascular glaucoma moderately.<sup>19</sup> Neovascularization of the optic disc occurs after about 2% of central retinal artery obstruction (Fig. 6.19.3).<sup>20</sup> Vitreous hemorrhage may ensue.

## DIAGNOSIS AND ANCILLARY TESTING

Diagnosis of central retinal artery obstruction is straightforward when diffuse ischemic retinal whitening is present in the setting of abrupt, painless visual loss. Fluorescein angiography may help if the diagnosis is in doubt. A delayed arm-to-retina time with a leading edge of dye visible in the retinal arteries is typical (see Fig. 6.19.1B). In some cases, it may be minutes before the retinal arterial tree fills with fluorescein. Arteriovenous transit is delayed as well, and late staining of the disc is common. Retinal oximetry may aid in early diagnosis and have utility for follow-up as it can demonstrate the return of blood flow, but this emerging modality requires further clinical testing.<sup>21</sup>

**Fig. 6.19.3** A 26-Year-Old Diabetic Man. (A) Central retinal artery obstruction caused by a platelet-fibrin embolus. (B) After 3 months, extensive neovascularization of the disc is present. (Courtesy Larry Magargal, MD.)

Macular optical coherence tomography (OCT) in the acute phase shows inner retinal thickening with shadowing of the outer retina that can be mistaken for subretinal fluid. When the retinal whitening resolves, OCT reveals severe inner retinal thinning.<sup>22</sup> OCT angiography of prior central retinal artery obstruction demonstrates decreased retinal vascularity and attenuation of vessels in the macula (Fig. 6.19.4). Electroretinography characteristically reveals a decreased to absent b-wave with intact a-wave. Visual fields show a remaining temporal island of peripheral vision. If a patent cilioretinal artery is present, a small intact central island is found as well.

Color Doppler imaging is a form of ultrasonography that can help to determine the blood flow characteristics of the retinobulbar circulation. Color Doppler studies of acute central retinal artery obstruction show diminished to absent blood flow velocity in the central retinal artery, generally with intact flow in the ophthalmic and choroidal branches. Color Doppler imaging can be used to detect calcific emboli at the lamina cribrosa and may be used to monitor blood flow changes induced by therapy.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of central retinal artery obstruction is given in Box 6.19.2.

**Fig. 6.19.4** Optical Coherence Tomography Angiography and Corresponding Optical Coherence Tomography Structural B-Scan From an Eye With a Prior Central Retinal Artery Obstruction. Note the paucity of small retinal vessels in the macula and the attenuation of the large retinal vessels. Structural B-scan shows loss of inner retinal tissue.

### BOX 6.19.2 Differential Diagnosis of Central Retinal Artery Obstruction

- Single or multiple branch retinal artery obstruction
- Cilioretinal artery obstruction
- Severe commotio retinas
- Necrotizing herpetic retinitis

## SYSTEMIC ASSOCIATIONS

Although systemic diseases commonly are found in patients who suffer from retinal artery obstruction, the true cause and effect may not be clear. About 50%–60% of patients have concurrent systemic arterial hypertension, and diabetes is present in 25%. Systemic evaluation reveals no definite cause for the obstruction in over 50% of affected patients. Potential embolic sources are found in less than 40% of cases.<sup>23,24</sup>

The most common pathogenetic association uncovered is hemodynamically significant ipsilateral carotid artery disease, which is present in about one-third of affected patients. Carotid noninvasive testing should be considered for all patients who have central retinal artery obstruction, although disease in those younger than 50 years of age is quite rare (Fig. 6.19.5). An embolic source from the heart is present in less than 10% of patients with central retinal artery obstruction, but echocardiography and Holter monitoring should be performed, especially in younger patients. In some cases, transesophageal echocardiography is necessary to reveal embolic sources.<sup>25</sup> In a large, population-based study, subjects with history of retinal artery obstruction were two times more likely to have a stroke than controls.<sup>26</sup>

Even though it is present in less than 5% of cases, it is of paramount importance that temporal arteritis be ruled out in all patients older than 50 years who have a central retinal artery obstruction. An immediate erythrocyte sedimentation rate must be obtained, and if it is elevated or if clinical

**Fig. 6.19.5 Acute Central Retinal Artery Obstruction.** Secondary to an embolus at the lamina cribrosa. Note two other emboli in the superior retinal vessels. Ipsilateral carotid artery disease was present.

suspicion exists, corticosteroid therapy and a temporal artery biopsy are considered.

Other rare associated systemic diseases include blood-clotting abnormalities such as antiphospholipid antibodies, protein S deficiency, protein C deficiency, and antithrombin III deficiency.<sup>27,28</sup> A list of systemic associations for retinal artery obstructions is given in [Box 6.19.3](#).

## **PATHOLOGY**

Histopathological examination shows coagulative necrosis of the inner retina. Acute, early, intracellular edema is followed by complete loss of the inner retinal tissue. Chronically, a diffuse acellular zone replaces the nerve fiber layer, ganglion cell layer, and inner plexiform layer. The outer retinal cells remain relatively intact. Sections of the obstructed central retinal artery may reveal a thrombus or embolus that is often recanalized ([Fig. 6.19.6](#)).

## **TREATMENT**

No proved treatment exists for central retinal artery obstruction, but treatment strategies center around the following goals:

- Increase retinal oxygenation.
- Increase retinal arterial blood flow.
- Reverse arterial obstruction.
- Prevent hypoxic retinal damage.

Theoretically, retinal oxygenation can be increased by breathing carbogen (95% oxygen, 5% carbon dioxide). No clinical study indicates efficacy for carbogen therapy, and one retrospective study suggests that it has no beneficial effect.<sup>29</sup> It is rarely used currently.

An increase in retinal arterial blood flow is attempted by lowering intraocular pressure. This is accomplished by ocular massage, paracentesis,

### **BOX 6.19.3 Systemic Conditions Associated With Retinal Artery Obstructions**

#### **Atherosclerotic Cardiovascular Disease**

- Ophthalmic artery plaques, stenosis, or dissection
- Carotid artery plaques, stenosis, or dissection
- Aortic plaques, stenosis, or dissection

#### **Cardiac**

- Valvular disease (including rheumatic fever)
- Ventriculoseptal defects
- Patent foramen ovale
- Papillary fibroelastoma
- Cardiac myxoma
- Mural thrombus
- Arrhythmias
- Subacute bacterial endocarditis

#### **Coagulopathies**

- Antiphospholipid antibodies
- Lupus anticoagulant
- Protein C deficiency
- Protein S deficiency
- Antithrombin III deficiency
- Elevation of platelet factor 4
- Prothrombin deficiency
- Sickle cell disease

#### **Oncological**

- Metastatic tumors
- Leukemia
- Lymphoma

#### **Radiological and Medical Procedures**

- Angiography
- Angioplasty
- Chiropractic neck manipulation
- Depot corticosteroid injection

#### **Systemic Vasculitis**

- Susac's disease
- Systemic lupus erythematosus
- Polyarteritis nodosa

- Temporal arteritis
- Scleroderma
- Sneddon–Wilkinson disease
- Wegener's granulomatosis
- Inflammatory bowel disease
- Kawasaki syndrome

#### **Systemic Infections**

- Syphilis
- Mediterranean spotted fever
- Loiasis
- Bartonella
- Dengue fever

#### **Local Trauma**

- Direct ocular compression
- Penetrating injury
- Retrobulbar injection
- Peribulbar injection
- Postretinal detachment repair
- Orbital trauma
- Retrobulbar hemorrhage
- Purtscher disease

#### **Local Ocular**

- Prepapillary arterial loops
- Optic nerve drusen
- Necrotizing herpetic retinitis
- Orbital mucormycosis
- Toxoplasmosis

#### **Miscellaneous**

- Amniotic fluid embolism
- Pancreatitis
- Migraine
- Pregnancy
- Oral contraceptives
- Cocaine abuse
- Intravenous drug use
- Viperine snakebite

**Fig. 6.19.6 Central Retinal Artery Occlusion.** (A) A trichrome-stained section shows an organized thrombus (T) that occludes the central retinal artery within the optic nerve (V, vein). (B) A histological section at the early stage shows edema of the inner neural retinal layers and ganglion cell nuclei pyknosis. Patient had a cherry-red spot in the fovea at time of enucleation. IM, Internal limiting membrane; IN, inner nuclear layer; NG, swollen nerve fiber and ganglion layers; ON, outer nuclear layer; OP, outer plexiform layer; PR, photoreceptors.

and the administration of ocular antihypertensive medications. Medical attempts to dilate retinal arteries or block vascular spasm have been tried as well. Hemodilution, sublingual nitroglycerin, pentoxifylline (oxpentifylline), calcium-channel blockers, and  $\beta$ -blockers have all been used with no proof of efficacy.<sup>30,31</sup>

Reversal of arterial obstruction through the use of anticoagulation or fibrinolytic medications has been reported. To date, the utility of these interventions has not been proved by controlled clinical trials. The only prospective, controlled trial of intra-arterial thrombolysis (EAGLE Study) was unable to show a benefit compared to conventional therapy although the power of the study was low.<sup>32</sup>

Thrombolysis can also be achieved intravenously as per stroke thrombolysis protocol. An interventional case series demonstrated that intravenous tPA with concomitant intravenous heparin resulted in visual improvement of three Snellen lines or more in 50% of subjects if given within 6.5 hours after onset of symptoms.<sup>33</sup> The results of a small, randomized, controlled trial also suggest that intravenous tPA is efficacious only when given within 6 hours of onset of symptoms.

At present, prevention of hypoxic damage to the retina is only theoretically possible.<sup>34</sup> Antioxidant medications (e.g., superoxide dismutase) and *N*-methyl-D-aspartate (NMDA) inhibitors are two classes of compounds that may accomplish retinal rescue pharmacologically and are under study. Hyperbaric oxygen therapy with hemodilution can also be used.<sup>35</sup>

Cases of central retinal artery obstruction associated with temporal arteritis are treated emergently with high-dose corticosteroids. Without therapy, the risk to the second eye is great. Although the first affected eye rarely recovers, instances exist in which high-dose intravenous methylprednisolone induced visual recovery from central retinal artery obstruction associated with temporal arteritis.<sup>36</sup>

## COURSE AND OUTCOME

Most central retinal artery obstructions result in severe, permanent loss of vision. About one-third of patients experience some improvement in final vision in terms of presentation acuity either with or without conventional treatment. Three or more Snellen lines of improved visual acuity occur in only about 10% of untreated patients.

Experimentally, if an obstruction exists in the primate retina for more than 240 minutes, complete irreversible death of the inner retina occurs.<sup>37</sup> In practice, a rare patient has experienced total spontaneous recovery even after several days of documented visual loss.<sup>38</sup> Spontaneous recovery may be more common in young children.

## BRANCH RETINAL ARTERY OBSTRUCTION

### INTRODUCTION

Branch retinal artery obstruction represents a rarely encountered retinal vascular disorder. Although current treatments are not effective, in the majority of cases the source of the obstruction can be determined. As associated systemic implications occur, diagnosis and systemic evaluation of these patients are critical.

### EPIDEMIOLOGY AND PATHOGENESIS

Branch retinal artery obstruction is a rare event, even less common than central retinal artery obstruction overall. The exception to this comparative incidence is with young patients, in whom branch retinal artery obstruction is the more common type of retinal artery obstruction.<sup>39</sup> Overall, men are more affected than women by a 2:1 ratio, which reflects the higher incidence of vasculopathic disease in men. In the subset of young patients (less than 50 years of age), women and men are affected equally. The mean age of affected patients is 60 years, with a range from the second decade of life to the tenth. The great majority of patients are in the sixth or seventh decade of life. The right eye (60%) is affected more commonly than the left (40%), which probably reflects the greater possibility of cardiac or aortic emboli traveling to the right carotid artery. Branch retinal artery obstruction strikes the temporal retinal circulation far more frequently than the nasal, consistent with the greater blood flow to the macular retina.<sup>40</sup>

Over two-thirds of branch retinal artery obstructions are secondary to emboli to the retinal circulation.<sup>41</sup> In most cases, the emboli are clearly visible in the arterial tree. Emboli to the retinal circulation may originate at any point in the proximal circulation from the heart to the ophthalmic artery. Risk factors reflect the vasculopathic mechanisms that produce disease within the cardiovascular system. These include predisposing family history, hypertension, elevated lipid levels, cigarette smoking, and diabetes mellitus.

Three main types of retinal emboli have been identified:

- Cholesterol (Hollenhorst plaque).
- Platelet-fibrin.
- Calcific.

Cholesterol emboli typically emanate from atheromatous plaques of the ipsilateral carotid artery system, although the aorta or heart valves may also be a source. They are yellow-orange in color, refractile, and globular or rectangular in shape. They may be small and can on occasion be seen intravascularly without blockage of blood flow. Platelet-fibrin emboli are long, smooth, white-colored, intra-arterial plugs that may be mobile or break up over time. Usually they are associated with carotid or cardiac thromboses. Calcific emboli are solid, white, nonrefractile plugs associated with calcification of heart valves or the aorta.

Less commonly seen embolic types include tumor cells from atrial myxoma<sup>42</sup> or a systemic metastasis, septic emboli associated with septicemia or endocarditis, fat emboli associated with large bone fractures, emboli dislodged during angioplasty or angiography, and depot drug preparations from intra-arterial injections around the eye or face.

Rarely, local ocular conditions produce branch retinal artery obstruction. These include inflammatory diseases such as toxoplasmosis<sup>43</sup> or acute retinal necrosis, mechanical compression from anterior ischemic optic neuropathy,<sup>44</sup> or structural entities such as optic disc drusen or prepapillary arterial loops.

Systemic hematological or clotting problems may induce isolated branch retinal artery obstruction or even multiple recurrent branch retinal artery obstruction.<sup>45,46</sup> Systemic vasculitides, such as polyarteritis nodosa

**Fig. 6.19.7 Superior Hemispheric Branch Retinal Artery Obstruction.** The site of obstruction is probably within the optic nerve substance itself. Note that the dual trunk of the central retinal artery obstruction has separated proximal to the lamina. Only the superior trunk was affected.

or local vasculitis associated with varicella infection, may be associated with branch retinal artery obstruction. Oral contraceptive use and cigarette smoking have been implicated as possible risk factors, especially in young, otherwise healthy women.

## OCULAR MANIFESTATIONS

Abrupt, painless loss of vision in the visual field corresponding to the territory of the obstructed artery is the typical history of presentation. Amaurosis fugax occurs in about one-fourth of patients prior to frank obstruction, especially in the setting of carotid disease. Rarely, patients develop bilateral simultaneous branch retinal artery obstruction, which can mimic homonymous field defects.

Acutely, examination reveals intact central acuity in about 50% of patients. A relative afferent pupillary defect is common, the presence of which is determined by the extent of retinal involvement.

Retinal whitening that corresponds to the areas of ischemia is the most notable finding. The whitening stops at adjacent retinal veins, as these vessels mark the extent of the territory of the retinal arteries (Fig. 6.19.7). Retinal emboli are seen in over two-thirds of branch retinal artery obstructions. Flame hemorrhages at the margins of the retinal ischemia are not uncommon, and local areas of more intense inner retinal whitening that resemble scattered cotton-wool spots can develop. Other areas with less intense retinal whitening may represent paracentral acute middle maculopathy (PAMM) lesions.<sup>47</sup>

A syndrome of multiple, recurrent, bilateral branch retinal artery obstruction in young, otherwise healthy patients has been reported. A few of the patients also manifest vestibuloauditory symptoms.<sup>48</sup> Although the underlying pathology in this subset of patients is probably heterogeneous, some probably have Susac's syndrome, a rare disorder that manifests as a microangiopathy of the central nervous system. Others probably have various types of systemic clotting abnormalities.<sup>49</sup>

In the chronic phase, when the retinal whitening has diminished, a loss of the nerve fiber layer in the affected area may be apparent. In most instances, the affected retina appears normal. At the site of obstruction, localized sheathing of the arteriole is common. Arteriolar collaterals on the optic disc or at the site of obstruction may develop.

## DIAGNOSIS AND ANCILLARY TESTING

Ancillary testing is not usually necessary to make the diagnosis. Fluorescein angiography (FA) reveals an abrupt diminution in dye at the site of the obstruction and distally. Filling in the adjacent retinal veins is slow to absent, and late staining or even leakage from the embolus site may occur. OCT initially reveals thickening and hyperreflectivity consistent with intracellular edema of the inner retina in the territory of the obstructed artery.<sup>50</sup> Over time, the corresponding inner retina will be severely thinned. OCT

### BOX 6.19.4 Differential Diagnosis of Branch Retinal Artery Obstruction

- Cotton-wool spot(s)
- Central retinal artery obstruction
- Cilioretinal artery obstruction
- Retinal astrocytoma
- Inflammatory or infectious retinitis

angiography demonstrates vascular features that correlate with FA and provide improved visualization of the microvasculature compared to FA, suggesting potential utility in monitoring branch retinal artery obstruction resolution.<sup>51</sup>

Visual field testing can confirm the extent of visual loss and may pick up contralateral field loss from previous emboli or other associated conditions.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of branch retinal artery obstruction is given in Box 6.19.4.

## SYSTEMIC ASSOCIATIONS

Systemic evaluation of patients who have branch retinal artery obstruction discloses evidence of an embolic source from the carotid arteries or the heart, in many cases. Other rare systemic conditions associated with branch retinal artery obstruction include amniotic fluid embolism, pancreatitis, sickle-cell disease, homocystinuria, and Kawasaki disease. Young patients, especially those who have multiple or recurrent branch retinal artery obstruction, should be evaluated for systemic clotting abnormalities.

Branch retinal artery obstruction associated with temporal arteritis is exceedingly uncommon.<sup>52</sup> It is not usually necessary to obtain an erythrocyte sedimentation rate unless other evidence of temporal arteritis exists. Box 6.19.3 lists the systemic conditions most commonly associated with retinal artery obstructions.

## PATHOLOGY

Early coagulative necrosis of the inner layers of the neural retina, which are supplied by the retinal arterioles, is manifest by edema of the neuronal cells during the first few hours after arterial occlusion and becomes maximal within 24 hours. The intracellular swelling accounts for the gray retinal opacity seen clinically. If the area of coagulative necrosis is small and localized, it appears as a cotton-wool spot, the clinical manifestation of a microinfarct of the nerve fiber layer of the neural retina. The cytoïd body observed microscopically is a swollen, interrupted axon in the neural retinal nerve fiber layer. Histologically, the swollen end bulb superficially resembles a cell, hence the term cytoïd body. A collection of many cytoïd bodies, along with localized edema, marks the area of the microinfarct. A cotton-wool spot represents a localized accumulation of axoplasmic debris in the neural retinal nerve fiber layer and results from interruption of the orthograde or retrograde organelle transport in ganglion cell axons, that is, obstruction of axoplasmic flow.

The outer half of the neural retina is well preserved. The inner half of the neural retina, however, becomes "homogenized" into a diffuse, relatively acellular zone, which generally contains thick-walled retinal blood vessels. Because the glial cells die along with the other neural retinal elements, gliosis does not occur.

## TREATMENT

No proven treatment exists for branch retinal artery obstruction. Because the visual prognosis is much better for branch retinal artery obstruction than for central retinal artery obstruction, invasive therapeutic maneuvers of dubious utility are not typically performed. Rarely, ocular massage or paracentesis will successfully dislodge an embolus. Laser treatment has been employed to disrupt emboli, in some cases with improvement in the vision.<sup>53,54,55</sup>

One report suggests that hyperbaric oxygen therapy may improve the visual loss associated with multiple branch retinal artery obstruction in Susac's syndrome.<sup>56</sup>

In the rare patient who has branch retinal artery obstruction accompanied by a systemic clotting disorder, systemic anticoagulation may prevent further events.

## COURSE AND OUTCOME

Most patients remain with a fixed visual field defect but intact central acuity. About 80% of eyes recover to 20/40 (6/12) or better central acuity. Retinal neovascularization has been reported but is distinctly uncommon. Iris neovascularization does not occur. In retrospective studies, greater foveal and outer nuclear layer thickness on OCT during the acute phase were positively correlated with improved vision in resolved branch retinal artery obstruction and thus may be useful prognostic factors.<sup>57,58</sup>

## OPHTHALMIC ARTERY OBSTRUCTION

Acute simultaneous obstruction of both the retinal and choroidal circulations is referred to as an ophthalmic artery obstruction. In some cases a single site of blockage in the ophthalmic artery is present, and in others simultaneous interruption of the retinal and posterior choroidal circulations with multiple blockage sites is found.

Ophthalmic artery obstructions can be differentiated clinically from central retinal artery obstruction by the following features:<sup>59</sup>

- Severe visual loss—bare or no light perception.
- Intense ischemic retinal whitening that extends beyond the macular area.
- Little to no cherry-red spot.
- Marked choroidal perfusion defects on fluorescein angiography.
- Nonrecordable electroretinogram.
- Late retinal pigment epithelium alterations.

Cases of ophthalmic artery obstruction usually have associated local orbital or systemic diseases, which include orbital mucormycosis, orbital trauma, retrobulbar anesthesia, depot corticosteroid injection, atrial myxoma, or carotid artery disease. Temporal arteritis usually does not produce ophthalmic artery obstruction in the absence of ipsilateral ischemic optic neuropathy.

As with central retinal artery obstruction, no proven therapy exists and significant visual recovery usually does not occur. In the absence of local causes, systemic evaluation must include testing for temporal arteritis, carotid artery disease, and cardiac disease.

## CILIORETINAL ARTERY OBSTRUCTION

A cilioretinal artery exists in about 30% of individuals. It is a vessel that perfuses the retina and is derived directly from the posterior ciliary circulation rather than from the central retinal artery. For this reason, it may remain patent in the setting of a central retinal artery obstruction. Such vessels are usually observed to emanate from the temporal disc margin. They may be multiple and can also perfuse the nasal retina. On fluorescein angiography, they fill 1–3 seconds prior to the retinal circulation. Cilioretinal artery obstruction exists in three clinical variations:

- Isolated
- Cilioretinal artery obstruction combined with central retinal vein obstruction
- Cilioretinal artery obstruction combined with ischemic optic neuropathy

Isolated cilioretinal artery obstructions usually occur in young patients in the setting of collagen vascular disorders. They carry a good visual prognosis, with 90% of eyes left with 20/40 (6/12) or better vision.<sup>60</sup>

Cilioretinal artery obstruction combined with central retinal vein obstruction is not an uncommon variant in young patients (Fig. 6.19.8). It generally behaves as a nonischemic central retinal vein obstruction with a good central visual prognosis. The scotoma from the artery obstruction is usually permanent. Although the mechanism of this association is unclear, it is hypothesized that some eyes harbor a primary optic disc vasculitis (papillophlebitis) that affects both the arterial and venous circulation.<sup>61</sup> It is more common in men than in women. Patients are generally healthy, but this entity has been associated with inflammatory bowel disease and leukemia.

In contrast to the first two groups discussed before, cilioretinal artery obstruction with ischemic optic neuropathy carries a grim visual prognosis and a strong association with temporal arteritis.

**Fig. 6.19.8 Cilioretinal Artery Obstruction in Conjunction With Mild Nonischemic Central Retinal Vein Obstruction.** Note the retinal whitening just inferior to the fovea in the distribution of the cilioretinal artery.

**Fig. 6.19.9 Combined Central Retinal Artery Obstruction and Central Retinal Vein Obstruction.** Visual acuity in this 21-year-old woman who had lupus was light perception, and neovascularization of the iris ensued.

## COMBINED ARTERY AND VEIN OBSTRUCTIONS

Central retinal artery obstruction combined with simultaneous central retinal vein obstruction rarely occurs. Patients typically present with acute, severe loss of vision. Examination shows a cherry-red spot combined with features of a central retinal vein obstruction, which include dilated, tortuous veins that have retinal hemorrhages in all four quadrants (Fig. 6.19.9).<sup>62</sup> Associated systemic or local disease is the rule—collagen vascular disorders, leukemia, orbital trauma, retrobulbar injections, and mucormycosis have been implicated. The visual prognosis is generally poor and the risk of neovascularization of the iris is about 75%. In exceptional cases, a patient may manifest spontaneous improvement.<sup>63</sup>

Branch retinal artery obstruction combined with simultaneous central retinal vein obstruction has also been reported.<sup>64</sup> This rare entity behaves as a central retinal vein obstruction. Interferon has been implicated.<sup>65</sup> Neovascularization of the iris is possible, but systemic associations other than hypertension and diabetes have not been confirmed. Treatment with hyperbaric oxygen and nadroparin calcium has been described.<sup>66</sup>

## Venous Occlusive Disease of the Retina

6.20

Shilpa J. Desai, Xuejing Chen, Jeffrey S. Heier

## CENTRAL RETINAL VEIN OCCLUSION

**Definition:** Occlusion of the central retinal vein at the lamina cribrosa.

## Key Features

- Retinal hemorrhages in all four quadrants.
- Dilated, tortuous veins in all four quadrants.

## Associated Features

- Optic disc edema.
- Macular edema.
- Submacular fluid.
- Cotton-wool spots.
- Capillary nonperfusion.
- Neovascularization of the iris, retina, or optic disc.
- Vitreous hemorrhage.
- Neovascular glaucoma.
- Optic disc venous – venous collateral vessels (opticociliary collateral vessels).

## BRANCH RETINAL VEIN OCCLUSION

**Definition:** Occlusion of a branch retinal vein.

## Key Features

- Retinal hemorrhages in the distribution of the obstructed branch retinal vein.
- Dilated, tortuous retinal vein in the distribution of the obstructed branch.

## Associated Features

- Optic disc edema.
- Macular edema.
- Submacular fluid.
- Cotton-wool spots.
- Capillary nonperfusion.
- Retinal neovascularization.
- Vitreous hemorrhage.

## INTRODUCTION

Venous occlusive disease of the retina is the second most common retinal vascular disorder, behind diabetic retinopathy.<sup>1</sup> It is believed to be caused by external compression of the vein by an atherosclerotic artery, intraluminal thrombosis, or inflammation of the vein<sup>2,3</sup> and typically affects patients 50 years of age or older. Retinal vein occlusions are usually recognized by

their characteristic clinical appearance, and treatment options have been investigated thoroughly with large, multicenter, randomized clinical trials.

Retinal vein occlusions are classified according to whether the central retinal vein or one of its branches is obstructed. Central retinal vein occlusion (CRVO) and branch retinal vein occlusion (BRVO) differ with respect to pathophysiology, underlying systemic associations, clinical course, and therapy. Branch retinal vein occlusions occur more frequently than CRVO.

## EPIDEMIOLOGY

The global impact of RVOs is significant, with an estimated 16.4 million adults affected worldwide—2.5 million affected by CRVO and 13.9 affected by BRVO.<sup>4,5</sup> Large, population-based studies have shown that the cumulative incidence of RVO over a 9–15 year period is 1.6%–3.0% in the elderly population,<sup>1,6</sup> with a 9–15 year cumulative incidence of CRVO at 0.3%–0.5% and BRVO at 1.6%–2.7%.<sup>6–8</sup> Using pooled data from populations in the United States, Europe, Asia, and Australia, the estimated prevalence of BRVO is 4.42 per 1000 people and CRVO is 0.8 per 1000 people, increasing with age.<sup>4</sup> Additionally, CRVO is associated with an increase in mortality because of its statistical association with comorbid diabetes or cardiovascular disease.<sup>9</sup> The presence of glaucoma is frequently found to be a risk factor for the development of both CRVO and BRVO, with an odds ratio of 2.53 and 9.28, respectively<sup>6</sup>; however, the Beijing Eye Study did not find such an association.<sup>7</sup> Variations in the population-based studies are likely due to significant variations in sample ethnicity as well as differences in age eligibility for subjects. Bilaterality is uncommon in both CRVO and BRVO, with a coincident second RVO occurring in 6.3% eyes in the 15-year Beaver Dam Eye Study cohort,<sup>6</sup> in 6.4% of eyes after 5 years in the Blue Mountains Eye Study.<sup>1</sup> The risk of any vascular occlusion in an unaffected fellow eye has also been estimated to be 0.9% per year.<sup>10</sup>

Data on the economic burden of vein occlusions is limited. Using the Beaver Dam Eye Study estimates of prevalence in conjunction with a study on the Medicare cost per CRVO diagnosis based on 2006 dollars,<sup>11</sup> the total costs to the U.S. Medicare population are estimated to be \$1.3 billion annually for CRVO.<sup>12</sup>

## CENTRAL RETINAL VEIN OCCLUSION

## PATHOGENESIS

The occlusion is believed to be the result of a thrombus in the central retinal vein at or posterior to the lamina cribrosa. Arteriosclerosis of the neighboring central retinal artery that causes turbulent venous flow and then endothelial damage often is implicated. Endothelial cell proliferation has been suggested also. An alternative theory is that thrombosis of the central retinal vein is an end-stage phenomenon, induced by a variety of primary insults such as compressive or inflammatory optic nerve or orbital problems, structural abnormalities in the lamina cribrosa, or hemodynamic changes.

## OCULAR MANIFESTATIONS

The diagnosis of a CRVO is based on the characteristic fundus findings of dilated and tortuous retinal veins in all four quadrants of the retina in association with intraretinal hemorrhages, cotton-wool spots, retinal exudations, disc edema, and/or concurrent signs of hypertensive retinopathy (Fig. 6.20.1).<sup>13</sup> Macular edema and ischemia are the most common causes of vision loss; however, the presence of intraretinal hemorrhage and exudates in the fovea can also affect vision. Patients generally present with acute onset painless blurry vision although an incidental finding of a mild

**Fig. 6.20.1 Central Retinal Vein Occlusion.** Fluorescein angiogram with peripheral sweeps showing dilated and tortuous retinal veins with widespread blocking defects from intraretinal hemorrhage (see color fundus photograph inset) and far peripheral nonperfusion.

CRVO is possible. Rarely, patients can present with a combined retinal vein and artery occlusion, which typically lead to a poor visual prognosis.<sup>14,15</sup>

The severity of CRVOs often corresponds to the amount of retinal nonperfusion, which can easily be appreciated on fluorescein angiography. Vision for minimally nonperfused CRVOs can be mild to moderate, whereas highly nonperfused eyes can have an afferent pupillary defect with significant vision loss. Traditionally, CRVOs were categorized as non-ischemic CRVOs, which is defined as less than 10 disc areas of ischemia as seen on the traditional seven standard field fluorescein angiography, versus ischemic CRVOs, which encompasses all other eyes. This distinction between the two types of CRVOs remains somewhat arbitrary, representing a continuum of disease severity but has been an important separation in literature describing CRVO outcomes. Of all patients with CRVO, 75%–80% can be considered classically nonischemic (Fig. 6.20.2), whereas classic ischemic CRVOs account for 20%–25% of all CRVOs (Fig. 6.20.3). The Central Vein Occlusion Study (CVOS) Group found that 34% of nonischemic CRVOs progressed to become ischemic within 3 years.<sup>10</sup>

Ischemic CRVOs tend to have higher rates of neovascularization of the iris and/or angle,<sup>16,17</sup> which typically occur within 3 months of disease onset (90-day glaucoma), and the subsequent rate of neovascular glaucoma ranges from 20%–63% (compared to 0% in nonischemic CRVOs).<sup>18</sup> In the absence of neovascularization, the pathological clinical features of CRVOs may decrease or resolve 6–12 months after diagnosis. During the resolution phase, the optic nerve can show pallor and develop optociliary collateral vessels. Permanent macular changes can develop that include pigmentary changes, epiretinal membrane formation, and subretinal fibrosis. Macular ischemia or sequelae from persistent macular edema may ultimately limit final visual acuity, especially if there is significant peripheral nonperfusion.

In about 20% of eyes, the central retinal vein enters the optic nerve as two separate branches (superior and inferior) before merging as a single trunk posterior to the lamina cribrosa. In these eyes, occlusion of one of the dual trunks within the substance of the optic nerve results in a hemispheric CRVO. Although only one half of the retina is involved, these occlusions act like CRVOs in terms of visual outcome, risk of neovascularization, and response to treatment.

Some mild CRVOs in patients younger than 50 years are classified as papillophlebitis, a term that suggests a benign course. An inflammatory optic neuritis or vasculitis is hypothesized as the cause. These eyes tend to have optic disc edema out of proportion to the retinal findings, cotton-wool spots that ring the optic disc, and occasionally cilioretinal artery occlusions or even partial central retinal artery occlusions. Although spontaneous improvement is common, the course is not always benign. Up to 30% of these patients may develop the ischemic type of occlusion with a final visual acuity of 20/200 (6/60) or worse.<sup>19</sup>

## ANCILLARY TESTING

Fluorescein angiography for CRVOs show a delayed filling of the retinal veins and is the most useful ancillary test for the evaluation of nonperfusion

and neovascularization. The risk of a neovascular event increases with the extent of nonperfusion, particularly above 5.5 disc areas.<sup>20</sup> The CVOS Group reported that 35% of ischemic and 10% of nonischemic CRVOs demonstrated anterior segment (iris or angle or both) neovascularization at or before the 4-month follow-up.<sup>10</sup> They found the greatest predictors of anterior segment neovascularization were visual acuity and degree of nonperfusion on fluorescein angiography, the worst prognostic groups being patients with visual acuity worse than 20/200 (6/60) or 30 or more disc areas of nonperfusion.<sup>10</sup>

Fluorescein angiography in ischemic CRVOs may show marked hypofluorescence (see Fig. 6.20.3), which is secondary to either blockage from intraretinal hemorrhages or to retinal capillary nonperfusion. When extensive hemorrhages are present, grading the degree of ischemia can be difficult. However, as the hemorrhages clear, the degree of capillary nonperfusion typically becomes more apparent. A greater amount of initial hemorrhages is associated with a higher level of ischemia. Angiography can also reveal optic nerve head leakage and perivenous staining, and in the late stages of the disease, collateral vessels and microaneurysms can be seen. The macular region may also show persistent edema or pigmentary degeneration. With nonischemic CRVOs, fluorescein angiography can reveal staining along the retinal veins, microaneurysms, and dilated optic nerve head capillaries. Retinal capillary nonperfusion (see Fig. 6.20.2) is minimal or absent. As the nonischemic CRVO resolves, angiography may become normal. The appearance of atypical findings on fluorescein angiography, such as choroidal nonperfusion, should prompt consideration of other diagnoses.

The original definitions of ischemic and nonischemic CRVOs in the CVOS study relied on fluorescein angiography from the seven standard field images as defined by the Early Treatment of Diabetic Treatment Study.<sup>21</sup> With the advent of ultra-wide field imaging that can image up to 200° in one capture,<sup>22</sup> a growing number of studies are looking at the utility of assessing nonperfusion on a continuum. Different measurements of nonperfusion, including the ischemic index, total area of nonperfusion, and radial extent of nonperfusion, have all been proposed.<sup>22–25</sup>

Macular edema is the most common cause of visual loss in RVOs and can occur more severely in ischemic cases. Macular edema is best imaged by optical coherence tomography (OCT), which is useful in quantifying and monitoring macular edema in patients with RVOs.<sup>26,27</sup> OCT commonly shows subclinical serous detachments of the macula in up to 80% of patients.<sup>28</sup> ERM is also a common feature on OCT testing in the setting of an RVO.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis for CRVOs includes ocular ischemic syndrome, diabetic retinopathy, radiation retinopathy, hyperviscosity retinopathy, and hypertensive retinopathy with possible multiple contributing factors. Ocular ischemic syndrome often presents with attenuated vessels rather

**Fig. 6.20.2 Nonischemic Central Retinal Vein Occlusion.** (A) Fundus photograph and (B) fluorescein angiogram showing scattered intraretinal hemorrhages, mild optic nerve head edema and hyperemia, and dilated and tortuous veins. (C) Optical coherence tomography showing no significant macular edema.

**Fig. 6.20.3 Ischemic Central Retinal Vein Occlusion.** (A) Fundus photograph and (B) fluorescein angiogram showing extensive intraretinal hemorrhages. The vasculature is barely discernable. (C) Optical coherence tomography showing cystoid macular edema with subretinal fluid.

than dilated and tortuous veins, can have choroidal in addition to retinal nonperfusion, and can be associated with hypotony from ciliary body ischemia. Additionally, the retinal hemorrhages seen in ocular ischemic syndrome tend to localize to the midperiphery instead of the posterior pole as seen in CRVO. Diabetic retinopathy requires the concurrent diagnosis of diabetes and is generally a bilateral disease. Radiation retinopathy requires an antecedent history of radiation affecting the periorbital region.

Hyperviscosity syndromes may produce a retinopathy similar to CRVO or BRVO. Simultaneous bilateral disease is an unusual finding in RVOs but occurs more commonly in hyperviscosity states seen in diseases like Waldenström's macroglobulinemia, polycythemia vera, leukemia, and multiple myeloma. Additionally, vasculitis that may be associated with

systemic inflammatory disease, such as sarcoidosis, Behçet's, and polyarteritis nodosa, can also masquerade as a CRVO.

When a patient presents with a CRVO in the absence of clear risk factors or presents with bilateral disease, the medical and laboratory evaluation should include a targeted search for evidence of diabetes, hyperviscosity syndromes, or inflammatory disease. Treatment of the primary disease can help improve the course of the retinopathy. For instance, plasmapheresis can be effective in reversing the retinopathy seen in cases of acute hyperviscosity syndrome.<sup>29</sup> Severe anemia with thrombocytopenia can also cause a retinopathy that resembles CRVO, which can be treated with transfusions. Lastly, acute hypertensive retinopathy with disc edema may resemble bilateral CRVO and require immediate lowering of blood pressure to prevent end-organ damage throughout the body.

**SYSTEMIC ASSOCIATIONS AND LABORATORY EVALUATION**

CRVO has been clearly associated with age greater than 50 years and hypertension. The association with hyperlipidemia, diabetes mellitus, and cardiovascular disease has been demonstrated in some studies but not others. These are the most common associations of CRVO, and in a patient over the age of 50 known to have one of these conditions, no further workup is necessary.

The absence of the above known risk factors, especially in a young patient,<sup>30</sup> should prompt a general medical evaluation, which can include a medical history and physical examination with blood pressure evaluation (Box 6.20.1). Basic laboratory evaluation may include a complete blood count, chemistry profile, coagulation factors, hemoglobin A1C, and lipid profile. If a systemic clotting diathesis, blood dyscrasia, or hyperviscosity is suspected based on medical history and concurrent signs, further hematological work up is required. The workup should be driven by medical history and may need to be done in conjunction with a hematologist or rheumatologist. Relevant labs may include lupus anticoagulant, antiphospholipid antibody, anticardiolipin antibody, antithrombin III, factor V Leiden, serum protein electrophoresis, complement factors, and protein S and protein C levels. Elevated levels of homocysteine have also been associated with the development of retinal vascular occlusive disease.<sup>31</sup> If there are signs of inflammation, an autoimmune vasculitis must be ruled out with laboratory work and/or imaging. Oral contraceptive use in women has also been associated with CRVO.<sup>32</sup>

**PATHOLOGY**

Green et al.<sup>2</sup> evaluated histological sections of 29 eyes in 28 patients who had CRVO. All 29 eyes had the formation of a fresh or recanalized thrombus at or just posterior to the lamina cribrosa. There was a mild lymphocytic infiltration with prominent endothelial cells within the thrombi. Further, there was loss of the inner retinal layers consistent with inner retinal ischemia. Alterations in blood flow, hyperviscosity, and vessel wall abnormalities may produce CRVOs by enabling a thrombus of the central retinal vein to form. It has been hypothesized that glaucoma, a risk factor for CRVO, causes stretching and compression of the lamina cribrosa, which results in vessel distortion, increased resistance to flow, and, ultimately, thrombosis.<sup>2</sup>

**TREATMENT**

No known treatment reverses the pathology seen in CRVO. It is prudent to advise risk factor reduction along with a healthy diet and exercise. Several therapies have been proposed but none have proven efficacious, including aspirin; systemic anticoagulation with warfarin, heparin, and recombinant tissue plasminogen activator; local anticoagulation with intravitreal recombinant tissue plasminogen activator; corticosteroids; anti-inflammatory agents; isovolemic hemodilution; plasmapheresis; and optic nerve sheath

**BOX 6.20.2 Treatment Guidelines for Patients Who Have Central Retinal Vein Occlusion**

- Treat any associated intraocular neovascularization with panretinal photocoagulation.
- Treat associated macular edema, if visually significant, with an intravitreal anti-vascular endothelial growth factor (VEGF) agent or corticosteroid.
- Visual acuity loss from macular edema does not improve with grid laser.
- Lower intraocular pressure if elevated.
- Treat underlying medical conditions.

decompression. However, certain complications of CRVO, such as macular edema and neovascularization may be treatable (Box 6.20.2).

**Neovascular Glaucoma**

Neovascular glaucoma (NVG) is a severe complication of ischemic CRVO, and its hallmark is abnormal neovascularization of the iris (NVI) and angle (NVA). This may result in intractable glaucoma, blindness, and pain necessitating enucleation. The 3-year cumulative incidence of NVI or NVG in CRVO is 8.5%.<sup>20</sup> The CVOS Group investigated whether prophylactic panretinal photocoagulation (PRP) was effective in preventing the development of NVI or NVA in patients with ischemic CRVO.<sup>33</sup> The study found that prophylactically treated ischemic eyes developed NVI less frequently than ischemic eyes that were not treated prophylactically (20% in the treatment group versus 35% in the no-early-treatment group), although the difference was not statistically significant. However, PRP was more likely to result in prompt regression of NVI in the previously untreated group versus the prophylactically treated group (56% versus 22%, respectively, after 1 month). As a result, for ischemic CRVO, frequent follow-up examinations during the early months and prompt PRP if NVI develops is the recommended treatment strategy to reduce the risk of developing NVG. Ultra-wide field angiography provides extensive visualization of peripheral nonperfusion in eyes with CRVO allowing for calculation of an “ischemic index,” which may be helpful to identify eyes earlier at highest risk for NVG.<sup>34</sup>

Identification of early NVI at the pupillary border is critical; examination of the undilated pupil is recommended. Routine gonioscopy also is suggested, because NVA can occur without NVI. Intravitreal anti-vascular endothelial growth factor (VEGF) drugs such as bevacizumab have become a useful adjunctive therapy in quickly reducing or eliminating neovascularization from the anterior segment in CRVO.<sup>35</sup> It is important to note that the effect of intravitreal anti-VEGF therapy is limited by the half-life of the drug.

**Macular Edema**

Cystoid macular edema (CME) and resulting macular dysfunction occur in virtually all patients with ischemic CRVO and in many patients with nonischemic CRVO. The CVOS evaluated the efficacy of macular grid photocoagulation in patients with CRVO and macular edema.<sup>36</sup> Although macular grid laser treatment reduced angiographic CME, the study did not find a difference in visual acuity between the treated and untreated groups. As a result, it is not recommended that macular grid photocoagulation be employed for the treatment of CME in CRVO (as opposed to BRVO, see later).

Local administration of a corticosteroid, particularly intravitreal triamcinolone, is commonly used off label to treat CME associated with CRVO.<sup>37</sup> The Standard Care Versus Corticosteroid for Retinal Vein Occlusion (SCORE) study evaluated 1 mg and 4 mg doses of preservative-free intravitreal triamcinolone compared to observation for the treatment of CME in CRVO.<sup>38</sup> They found significant improvements in visual acuity in both treatment groups compared to observation at 1 year ( $\geq 15$  letter gains in 27% of eyes in 1 mg group, 26% in 4 mg group, 7% in untreated group). Incidence of cataract formation and intraocular pressure rise was highest in the 4 mg group (33% and 35% respectively). The effect of intravitreal triamcinolone was temporary, requiring an average of 2.2 and 2.0 injections after 8 months in the 1 mg and 4 mg treatment groups, respectively, to maintain efficacy. This limited duration of efficacy of intravitreal triamcinolone prompted the development of sustained-release intravitreal corticosteroids. A sustained-release intravitreal dexamethasone implant

has gained U.S. Food and Drug Administration (FDA) approval for CME in CRVO and BRVO.<sup>39</sup> One year following treatment with a 0.7 mg implant at baseline and at 6 months, 29% of eyes with CRVO or BRVO experienced a visual acuity gain of 15 or more letters. In a subanalysis, the peak improvement in mean visual acuity in CRVO eyes was 8.7 letters and occurred 60 days following injection. Corticosteroid-induced intraocular pressure rises and cataract formation occurred but generally less frequently compared to those in the SCORE trial.

Prospective studies have proven the efficacy of anti-VEGF agents including bevacizumab,<sup>40,41</sup> which is used off label, and both ranibizumab<sup>42</sup> and aflibercept,<sup>43</sup> which are FDA approved, for the treatment of CME secondary to CRVO. Bevacizumab dosed every 6 weeks for 6 months significantly improved visual acuity compared to sham injection (14.1 letter gain versus 2.0 letter loss).<sup>41</sup> The ranibizumab for the treatment of macular edema after Central Retinal Vein Occlusion Study (CRUISE) found similar gains of 12.7 (0.3 mg group) and 14.9 (0.5 mg group) letters with monthly ranibizumab compared to 0.8 letters in the sham group at 6 months.<sup>42</sup> The HORIZON trial (open-label extension trial of ranibizumab for choroidal neovascularization) included 60% of patients who completed the 12-month CRUISE trial.<sup>44</sup> During the first 12 months of HORIZON, patients were treated as needed with 0.5 mg ranibizumab; the patients originally in the 0.5 mg ranibizumab arm of CRUISE required a mean of 3.5 injections during HORIZON. Some of the visual and anatomical gains achieved during monthly treatment were lost during as-needed treatment. The CRUISE and HORIZON results together have shown that long-term use of ranibizumab is well tolerated, and regular follow-up and treatment are required for optimal visual and anatomic outcomes. The COPERNICUS trial investigated intravitreal aflibercept dosed every 4 weeks for 6 months compared to sham and found significant visual acuity gains compared to sham (6 months: 17.3 letter gain versus 4.0 letter loss). Patients were then dosed as needed for an additional 6 months in both groups, and the initially sham-treated group never caught up in visual acuity gains (12 months: 16.2 letter gain versus 3.8 letter gain), suggesting a benefit of earlier initiation of treatment.<sup>43</sup> The CRYSTAL study also showed that patients with earlier initiation of treatment after the onset of CRVO had better overall visual acuity outcomes.<sup>45</sup> The GALILEO study showed 60.2% of patients treated with aflibercept monthly for 6 months gained 15 or more letters as compared to 20.1% in the sham arm.<sup>46</sup> Finally, the NEWTON study demonstrated that patients previously treated with bevacizumab and ranibizumab experienced a longer edema-free interval on aflibercept (62 days on aflibercept vs. 39 days on bevacizumab/ranibizumab).<sup>47</sup> Anti-VEGF therapy has become the standard of care for the treatment of CME secondary to CRVO due to the convincing results of these trials.

## COURSE AND OUTCOME

The prognosis for visual recovery is dependent on the subtype of CRVO. In general, the visual prognosis can be predicted from the visual acuity during initial evaluation. Patients who have nonischemic CRVOs may experience a complete recovery of vision, although this occurs in less than 10% of cases.<sup>48</sup> In the CVOS, which established natural history data on CRVO, baseline visual acuity tended to (but did not always) predict eventual visual acuity outcome, which in turn reflected the perfusion status of the retina.<sup>10</sup> For example, for eyes with presenting visual acuity of 20/40 or more, 65% maintained this range of visual acuity, whereas for eyes with presenting visual acuity of less than 20/200, 80% had visual acuity remaining this poor at the conclusion of the study. With newer treatment modalities (particularly anti-VEGF agents), the natural course of CRVO is being curtailed, and better visual acuity outcomes are now possible compared to the era of the CVOS, as evidenced by the SCORE and CRUISE studies.

In the era of the CVOS study, recommended follow-up examination intervals depended on the presenting visual acuity and degree of ischemia.<sup>10,33,49</sup> With the advent of anti-VEGF therapy, most patients with CRVO are followed monthly, at least initially, while undergoing monitoring and treatment for CME.

## BRANCH RETINAL VEIN OCCLUSION

### PATHOGENESIS

BRVOs occur approximately three times more commonly than CRVOs. Most epidemiological and histopathological evidence implicates arteriolar disease as the underlying pathogenesis. BRVO almost always occurs at an

arteriovenous crossing, where the artery and vein share a common adventitial sheath. The artery typically is anterior (innermost) to the vein.<sup>50</sup> It is postulated that a rigid, arteriosclerotic artery compresses the retinal vein, which results in turbulent blood flow and endothelial damage, followed by thrombosis and occlusion of the vein.

Rarely, local ocular diseases, especially of an inflammatory nature, can result in a secondary BRVO. This has been reported in diseases such as toxoplasmosis, Eales' disease, Behçet's syndrome, and ocular sarcoidosis. When an occlusion does not occur at the arteriovenous crossing, the possibility of an underlying retinochoroiditis or retinal vasculitis should be considered. Macroaneurysms, Coats' disease, retinal capillary hemangiomas, and optic disc drusen are also linked to BRVO.

## OCULAR MANIFESTATIONS

BRVO is a common retinal vascular disorder of the elderly, at least three times more common than CRVO. Visual loss from a BRVO usually is caused by macular edema, macular ischemia, or secondary effects of neovascularization. Patients with BRVO usually complain of sudden onset of blurred vision or a visual field defect. Flame-shaped intraretinal hemorrhages confined to the distribution of a retinal vein are characteristic (Figs. 6.20.4A and 6.20.5A). The distribution of the hemorrhages usually assumes a triangular configuration with the apex at the site of blockage. Mild occlusions are associated with a relatively small amount of hemorrhage, whereas complete occlusions result in extensive hemorrhages, cotton-wool spot formation, and widespread capillary nonperfusion. If the macula is involved, macular edema and ischemia may cause decreased visual acuity. Visual acuity typically ranges from 20/20 (6/6) to counting fingers. If the macula is spared, a BRVO may be asymptomatic. Occasionally a partial BRVO with little hemorrhage and edema may progress to a complete BRVO, with an increase in hemorrhage and edema with a corresponding decrease in visual acuity. BRVOs occur superotemporally 52.3% of the time, inferotemporally 38.5% of the time, and in the nasal quadrant 9.2% of the time.<sup>6</sup> Nasal quadrant BRVOs are likely underrepresented, as most are asymptomatic and thus these patients might not seek ophthalmic attention.

Retinal neovascularization occurs in approximately 20% of cases, but anterior segment neovascularization (NVI/NVA) and NVG are exceedingly rare, in contrast to CRVO. The incidence of retinal neovascularization rises with increasing area of retinal nonperfusion.<sup>51</sup> Retinal neovascularization typically develops within the first 6–12 months but may occur years later. Vitreous hemorrhage and tractional retinal detachment can result, which may require vitrectomy. Microaneurysm formation and lipid exudation may also be present. Capillary nonperfusion is seen best on fluorescein angiography in the later stages after the hemorrhages have cleared. Localized serous retinal detachment can also be seen in the acute setting of a BRVO, a feature that has become more apparent with the advent of OCT.<sup>52</sup>

Over time, the clinical features of an acute BRVO can become subtler so that the fundus can look almost normal. Collateral vessels and microvascular abnormalities usually develop. Collateral vessels crossing the horizontal raphe are a salient feature of BRVO, and their presence should prompt consideration of remote BRVO. The retinal vein may become sclerotic proximal to the site of blockage while the retinal artery that feeds the affected zone may become narrowed and sheathed. Epiretinal membrane and macular retinal pigment epithelial changes as a result of chronic CME sometimes are seen in the late phase of a BRVO.

## ANCILLARY TESTING

Fluorescein angiography is a helpful adjunct for both establishment of the diagnosis and guidance for treatment of a BRVO. Arteriolar filling may be slowed in a severe BRVO, but venous filling in the affected vessel is almost always delayed in the acute phase. Hypofluorescence caused by hemorrhage and capillary nonperfusion are common findings, and dilated, tortuous capillaries are seen. Collateral vessels may cross the horizontal raphe. The retinal vessels, particularly the vein walls near the site of the occlusion, may stain with fluorescein. If neovascularization is present, there is profuse localized leakage on the angiogram. In contrast, collateral vessels do not leak fluorescein. Macular edema, if present, is revealed clearly by fluorescein angiography and may involve the entire fovea or just several clock hours, depending on the distribution of the occlusion. Optical coherence testing has become essential for diagnosing and managing macular edema in patients with BRVO (see Figs. 6.20.4B and D and 6.20.5B and D).

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis of BRVO is shown in [Box 6.20.3](#).

## SYSTEMIC ASSOCIATIONS

Many associations have been made with BRVO, the most common being systemic cardiovascular disorders and age.<sup>53</sup> Others include peripheral vascular disease, increased body mass index, and glaucoma. Interestingly, as with CRVO, there is significant discrepancy in regards to definitive risk factor identification among various epidemiological studies of BRVO.

## PATHOLOGY

A histopathological study of nine BRVOs showed a fresh or recanalized thrombus at the site of the vein occlusion in all eyes.<sup>3</sup> Ischemic atrophy

of the retina was found in the distribution of the occlusion in most of the eyes. All eyes showed varied degrees of arteriosclerosis. No thrombus was noted in any of the arteries. Neovascularization of the disc and retina was noted in four eyes, and CME was present in five eyes.

## TREATMENT

The Branch Vein Occlusion Study (BVOS) was designed to evaluate the effect of laser photocoagulation on neovascularization, vitreous hemorrhage, and macular edema in BRVO.<sup>51,54</sup> Peripheral sectoral scatter laser photocoagulation reduced the rate of development of both neovascularization and vitreous hemorrhage.<sup>51</sup> There was no advantage in treatment before neovascularization occurred, even if extensive capillary nonperfusion existed. If laser is applied to all nonperfused BRVOs, a large percentage of patients will be treated unnecessarily ([Boxes 6.20.4](#) and [6.20.5](#)). When peripheral laser is indicated, fluorescein angiography can be helpful

#### BOX 6.20.3 Differential Diagnosis of Branch Retinal Vein Occlusion

- Hypertensive retinopathy
- Diabetic retinopathy
- Radiation retinopathy
- Macular telangiectasia
- Retinal angiomatous proliferation

#### BOX 6.20.4 Treatment Guidelines for Branch Retinal Vein Occlusion and Macular Edema

- Determine if decreased visual acuity is caused by macular edema versus macular nonperfusion based on fluorescein angiography.
- If macular edema explains visual loss, consider early treatment with intravitreal anti-vascular endothelial growth factor (VEGF) therapy.
- Macular edema can resolve spontaneously by 3 months in one-third of patients. Consider grid macular photocoagulation as an adjunct to intravitreal anti-VEGF therapy if needed.
- Intravitreal corticosteroid implants can be considered, especially in pseudophakic patients.
- If capillary nonperfusion explains decreased visual acuity, laser treatment is not advised.

**Fig. 6.20.6 Wide Field Angiography in Branch Retinal Vein Occlusion.** Ultra-wide field fluorescein angiogram shows extensive peripheral nonperfusion in the superior and temporal periphery. Corresponding optical coherence tomography (inset) shows superior macular edema.

#### **BOX 6.20.5 Treatment Guidelines for Branch Retinal Vein Occlusion and Neovascularization**

- Obtain a good-quality fluorescein angiography after retinal hemorrhages have cleared sufficiently.
- If more than five disc diameters of nonperfusion are present, the patient should be followed at 4-month intervals to see if the development of neovascularization occurs.
- If neovascularization develops, panretinal photocoagulation to the involved retinal sector should be applied using argon laser.

in guiding laser treatment by defining areas of peripheral capillary nonperfusion (Fig. 6.20.6). A scatter pattern of laser is performed in the affected sector. Vitreous surgery is employed occasionally for nonclearing vitreous hemorrhages, epiretinal membrane, or tractional retinal detachment with macular involvement.

Additionally, BVOS patients who had 20/40 (6/12) or worse vision and macular edema on fluorescein angiography were treated with focal laser in a grid pattern over the area of leakage (as seen with fluorescein angiography). Treated patients had reduced macular edema and improved visual acuity compared to untreated controls.<sup>54</sup> Because visual acuity and macular edema may improve spontaneously, patients were not treated with laser for at least 3 months after the development of the BRVO. Photocoagulation did not extend closer than the edge of the foveal avascular zone, nor did it extend peripherally beyond the major vascular arcades. A grid pattern of laser was applied to the area of capillary leakage (Fig. 6.20.7).

In patients with macular edema, one or multiple focal laser treatments (see Fig. 6.20.4) may be necessary to achieve efficacy.<sup>55</sup> There is some evidence that peripheral nonperfusion, which is best visualized with ultra-wide field angiography (see Fig. 6.20.6), plays a pathogenic role in cases with persistent macular edema despite macular grid laser.<sup>56</sup> Scatter laser to the nonperfused peripheral retina may assist in reducing macular edema in these cases.

As in CRVO, prospective randomized trials have been performed to evaluate intravitreal corticosteroids and intravitreal anti-VEGF agents in the treatment of macular edema associated with BRVO. The SCORE study for BRVO found no improvement in visual acuity outcomes with intravitreal triamcinolone compared to standard grid macular laser treatment for macular edema.<sup>57</sup> Investigators did find higher rates of adverse events (cataract and elevated intraocular pressure) in the corticosteroid groups. The dexamethasone sustained release implant is approved for the treatment of macular edema in BRVO as well as CRVO, and a subanalysis for BRVO showed that nearly 30% of patients gained three or more lines of vision at 60 days, gaining an average of 10.3 letters. The rate of cataract progression

**Fig. 6.20.7 Branch Retinal Vein Occlusion.** Immediate posttreatment view of grid laser treatment for macular edema secondary to a BRVO.

and intraocular pressure elevation was lower for the dexamethasone implant than in the SCORE study, although data in the dexamethasone studies was only available for 6 months, after a maximum of two injections of the implant.

The ranibizumab for the treatment of macular edema following Branch Retinal Vein Occlusion (BRAVO) clinical trial found gains of 16.6 (0.3 mg group) and 18.3 (0.5 mg group) letters in the monthly ranibizumab groups compared with 7.3 in the sham group at 6 months.<sup>58</sup> As for CRVO, the HORIZON study was an open-label extension trial that included 67% of BRVO patients completing the 12-month BRAVO trial. Patients originally randomized to the 0.5 mg ranibizumab arm in BRAVO received a mean of 2.1 injections during 12 months of as-needed treatment in HORIZON.<sup>44</sup> Mean BCVA remained stable for the first 12 months of the HORIZON trial for BRVO patients. The reduction in frequency of ranibizumab injections (as needed compared to monthly) during this second year of follow-up had minimal functional or anatomical effect in BRVO patients, in contrast to the diminished gains observed in CRVO patients (see earlier). This difference may be due to the lower overall ischemic burden and concomitant VEGF load seen in BRVOs compared to CRVOs. The use of grid laser in some of the BRVO patients also may have contributed to better stability by decreasing the VEGF load.<sup>44</sup> In addition to ranibizumab, bevacizumab,

which is used off label, is also widely used in the treatment of macular edema due to BRVO.<sup>59</sup>

Given multiple treatment options, recent studies have compared the efficacy of laser versus injections. The VIBRANT study compared treatment with monthly aflibercept vs. grid laser for BRVO-related CME. At 24 weeks, BCVA was improved 17.0 letters in the aflibercept group vs. 6.9 letters in the grid laser group.<sup>60</sup> The RELATE trial also evaluated the benefit of grid laser.<sup>61</sup> This study initially randomized patients to receive ranibizumab vs. sham for macular edema secondary to BRVO. Twenty-four weeks after randomization, patients could receive combination of grid and scatter laser. The study found no additional benefit of laser in terms of improvement in vision, resolution of macular edema, or reduced number of intravitreal injections. Finally, the BRIGHTER trial compared grid laser monotherapy vs. ranibizumab monotherapy vs. ranibizumab plus grid laser. This study found no additional benefit to using grid laser vs. ranibizumab alone.<sup>62</sup>

In light of these studies, anti-VEGF therapy has become the standard treatment of CME due to BRVO (see Fig. 6.20.5). Questions remain regarding treatment duration and frequency, with long-term studies still being conducted.

## COURSE AND OUTCOME

Without treatment, one third of patients with BRVO end up with visual acuity better than 20/40 (6/12). However, two thirds have decreased visual acuity secondary to macular edema, macular ischemia, macular hemorrhage, or vitreous hemorrhage. As noted earlier, laser treatment for macular edema significantly enhances the chance that the patient's baseline visual acuity will improve by two lines (65% versus 37%).<sup>54</sup> With the advent of anti-VEGF therapy, treatment is often initiated earlier, and visual acuity outcomes are potentially more robust compared with treatment with focal laser alone. Poor visual prognostic factors include advancing age, male sex, worse baseline visual acuity, and an increased number of predisposing risk factors.<sup>63</sup>

Approximately 20% of patients with BRVO will develop neovascularization. Of these patients, about 60% will have episodic vitreous hemorrhages, the incidence of which can be reduced by sectoral PRP.

# Retinopathy of Prematurity

Aristomenis Thanos, Kimberly A. Drenser, Antonio Capone, Jr.

## 6.21

**Definition:** A proliferative retinopathy of premature infants.

### Key Features

#### Avascular Retina

- Stage 1: demarcation line between normal and avascular retina.
- Stage 2: elevated ridge between normal and avascular retina.
- Stage 3: extraretinal fibrovascular proliferation on the ridge.
- Stages 4 and 5: tractional retinal detachment due to contraction of extraretinal fibrovascular proliferation.

### Associated Features

- Low birth weight and gestational age.
- Dilated and tortuous arteries and veins in the posterior pole (plus disease).
- Macular ectopia and distortion.
- Tractional retinal detachment.
- Retinal fold.
- Leukocoria.

## INTRODUCTION

First described in 1942, retinopathy of prematurity (ROP) is a proliferative retinopathy affecting premature infants of low birth weight (BW) and young gestational age (GA).<sup>1</sup> Despite—and partly due to—major advances in neonatology, ROP remains a leading cause of lifelong visual impairment among children in developed countries. About 1100–1500 infants annually in the United States develop ROP that is severe enough to require medical treatment, and of them 400–600 infants each year in the United States become legally blind from ROP.<sup>2</sup>

## PATHOGENESIS

The pathogenesis of ROP is multifactorial where developmental, genetic, and environmental factors come into play. During normal retinal development, vasculogenesis transforms precursor mesenchymal cells into capillary networks beginning at about 16 weeks of gestation.<sup>3</sup> Mature vessels differentiate from these networks and reach the nasal and temporal ora serrata at about 36 and 39–41 weeks, respectively. Therefore, full retinal vascular development is mostly accomplished in utero, where the fetus is in a relatively hypoxic environment (average PaO<sub>2</sub> is 25–35) and exposed to the placental and maternal cytokines and growth factors. In addition, several pivotal cell-signaling pathways and growth factors involved in retinal vasculogenesis and neural development—including the VEGF-signaling pathway,<sup>4</sup> insulin-like growth factor 1 (IGF-1),<sup>5</sup> and the Wnt-signaling pathway<sup>6</sup>—are disrupted by premature birth and the ex utero hyperoxic environment. Taken together, premature birth disrupts this well-orchestrated process, as the fetus is exposed to a new environment, and the ophthalmoscopic findings of ROP stem from this arrested development and aberrant retinal tissue response to it.

High oxygen administration at birth was among the first factors to be found critical to the pathogenesis of ROP.<sup>7</sup> Excessively high levels of oxygen in incubators, used to save the lives of premature infants, led to an ROP epidemic and the realization that reducing the level of oxygen given to premature babies reduces the incidence of ROP.<sup>8</sup> The detrimental effects of high and/or fluctuating oxygen concentrations were validated in the oxygen-induced retinopathy models, where alternating

oxygen concentrations induce retinal neovascularization.<sup>9,10</sup> Although these models lack significant features of human ROP [absence of ridge tissue, involution of retinal neovascularization (RNV), and absence of neovascular complications such as hemorrhage and tractional retinal detachment], they have been instrumental in the dissection of the molecular mechanisms involved in ROP and retinal neovascular diseases in general.

The association between high oxygen levels and ROP led to the development of the two-phase hypothesis for ROP almost 30 years before the classification of human ROP in zones and stages. According to this, in the first phase there is a delay or halting in physiological retinal vascular development due to prematurity as well as hyperoxia-induced endothelial cell damage and subsequent vasoattenuation. As the peripheral avascular retina continues to develop in the absence of a developing vascular bed, it becomes relatively hypoxic and secretes proangiogenic factors, which promote retinal neovascularization and abnormal vasoproliferation in the vitreous (second phase).

Given its pivotal role in other retinal neovascular diseases, increasing attention has been focused on vascular endothelial growth factor (VEGF).<sup>11</sup> In ROP, VEGF has been shown to be elevated in both the vitreous<sup>12</sup> and serum<sup>13</sup> of infants with ROP, and the importance of VEGF upregulation in the proliferative phase of this disease has been shown in humans, since blockade of VEGF with anti-VEGF antibodies (bevacizumab) has considerable efficacy.<sup>14</sup> However, this dual role of VEGF in development and disease raises concerns about the timing and safety of VEGF inhibition in ROP (discussed later).

Genetic factors may play a role in the development of severe ROP as well.<sup>15</sup> Some clinical features of ROP noted in near-term and full-term infants may resemble those seen in familial exudative vitreoretinopathy (FEVR), the X-linked form of which is associated with mutations in the Norrie's disease (NDP) gene.<sup>16</sup> Shastri et al. investigated a cohort of 16 premature infants with ROP and found missense mutations in four infants with advanced disease.<sup>17</sup> None of the parents or 50 healthy controls had mutations.<sup>17</sup> The NDP gene product, norrin, is a ligand that activates a signal transduction pathway necessary for early retinal development and vasculogenesis.<sup>18</sup> Subsequent studies have suggested up to 2% of infants with ROP have NDP mutations.<sup>19,20</sup> It is likely that other genes involved in this signal transduction pathway may harbor mutations or polymorphisms that predispose premature babies to increased rates of ROP.<sup>21</sup>

## CLINICAL FEATURES AND CLASSIFICATION

The International Classification of Retinopathy of Prematurity (ICROP) was instrumental in establishing the standards and nomenclature for the clinical assessment of ROP based on the anatomical location (zone) and severity (stage) of disease.<sup>22</sup> Zone I is defined as a circle, the center of which is the disc and the radius of which is twice the distance of the disc to the fovea. Zone II is a doughnut-shaped region that extends from the anterior border of zone I to within one disc-diameter of the ora serrata nasally and to the anatomical equator temporally. Zone III encompasses the residual temporal retina (Fig. 6.21.1).

The first sign of ROP (stage 1) is the appearance of a thin, flat, white structure (termed a demarcation line) at the junction of vascularized retina posteriorly and avascular retina anteriorly (Fig. 6.21.2A). Stage 2 ROP occurs as the demarcation line develops into a pink or white elevation (ridge) of thickened tissue (Fig. 6.21.2B); small tufts of vessels may be seen posterior to the ridge. Vessel growth into and above the ridge (extraretinal fibrovascular proliferation) characterizes stage 3 ROP (Fig. 6.21.2C). This fibrovascular proliferation may extend into the overlying vitreous and cause preretinal or vitreous hemorrhage (Fig. 6.21.2C). Contraction of fibrovascular proliferation exerts traction on the retina, leading to partial retinal detachment (stage 4 ROP), either without foveal involvement (stage

**Fig. 6.21.1 Anatomical Classification of Retinopathy of Prematurity by Zone.** The temporal edge of zone II coincides with the equator.

4A) (Fig. 6.21.2D) or with foveal involvement (stage 4B) (Fig. 6.21.2E). Stage 5 ROP denotes a total retinal detachment (Fig. 6.21.2F). Stage 5 detachments are funnel shaped and described as open or closed anteriorly and open or closed posteriorly. The term *retrolental fibroplasia*, originally coined by Terry in 1942,<sup>87</sup> refers to what we know today as stage 5 ROP.

In its acute (neovascular) phase, ROP is a progressive vascular disease with increasing dilatation and tortuosity of peripheral retinal vessels, engorgement of iris vessels, and pupillary rigidity. “Plus disease” refers to the presence of marked venous dilatation and arterial tortuosity in the posterior pole (Fig. 6.21.3A) secondary to arteriovenous shunting at the level of the ridge and constitutes the hallmark of progressive, treatment-warranting ROP. In the CRYO-ROP Study, plus disease was defined as significant dilation and tortuosity in all four vascular arcade quadrants, yet in subsequent studies<sup>23</sup> (STOP-ROP, ET-ROP) and current practice, the diagnosis of plus disease is made if sufficient vascular dilation and tortuosity are present in at least two quadrants of the eye. The term pre-plus disease was introduced later<sup>24</sup> to highlight the fact that plus disease does not appear as an all-at-once phenomenon but as a continuum of progressively increasing neovascular activity at the ridge manifested with arborization and tortuosity of the blood vessels (Fig. 6.21.3B). To this aim, pre-plus disease is defined as increased dilation and/or tortuosity of retinal arteries and/or veins in at least two quadrants, of insufficient severity for the diagnosis of plus disease. The presence of pre-plus disease can be predictive of progression to severe ROP requiring laser treatment.<sup>25</sup>

Aggressive posterior ROP (AP-ROP) is an uncommon severe form of ROP encountered in extremely premature infants (23–26 GA on average in some series<sup>26</sup>) that is characterized by very posterior (zone I) disease, neovascular fronds that lie flat on the retinal surface (flat neovascularization), absence of ridge tissue, and dilated tortuous vessels in a syncytial pattern (Fig. 6.21.3C).<sup>24</sup> AP-ROP can progress rapidly to stage 4 and 5 if left untreated, and eyes with AP-ROP have poorer prognosis than classic (zone II disease) ROP, with retinal detachment rates as high as 45%.<sup>27,28</sup>

Finally, the definition of “threshold” ROP has varied in successive clinical trials. In the CRYO-ROP study it was defined as the severity of ROP for which there was an equal chance of spontaneous regression or progression to an unfavorable outcome.<sup>29</sup> This was defined as stage 3+ ROP in zones I or II, occupying at least five contiguous clock-hours or eight noncontiguous clock-hours of retina.<sup>29</sup> For eyes with zone II ROP, this estimation proved quite precise: 62% of untreated eyes with threshold ROP went on to an untoward visual outcome.<sup>30</sup> However, untreated threshold zone I eyes had a 90% chance of unfavorable outcome. Roughly 44% of eyes with zone II ROP in the CRYO-ROP had an unfavorable outcome despite appropriate intervention.<sup>31</sup> To address this problem, the multicenter study of Early Treatment for Retinopathy of Prematurity (ETROP)<sup>32</sup> compared early treatment of high-risk eyes (prethreshold type 1) versus treatment at threshold to show that early laser treatment improves both structural and visual outcomes. Two categories of prethreshold disease were created and management dictated by high-risk (type 1) or low-risk (type 2) prethreshold disease. ETROP findings suggest that type 1 prethreshold ROP receive laser ablation of the peripheral avascular retina. Type 2 prethreshold ROP is observed weekly or twice weekly based on the extent of ROP noted. When compared to the results of the CRYO-ROP study, the ETROP study suggests that early treatment of high-risk prethreshold ROP significantly

decreases unfavorable visual acuity outcomes (19.5%–14.5%;  $p = 0.01$ ) and structural outcomes (15.6%–9.1%;  $p < 0.001$ ).

## DIAGNOSIS AND SCREENING

Initial examination of the anterior segment is performed with specific attention to the iris vessels, lens, and tunica vasculosa lentis. Poor pupillary dilation and iris vascular engorgement can be a sign of plus disease.<sup>22</sup> After pupillary dilation, fundus examination is performed with an indirect ophthalmoscope and a 28.00 diopter (D) or 30.00 D lens. The posterior pole is examined without depression for plus disease. Clinically, the entire zone I can be seen through a 28.00 D lens when the view is centered on the optic nerve. Scleral depression is then used to examine the temporal retina, followed by the nasal retina, to establish the proximity of retinal vessels to the ora serrata.

Given the progressive nature of ROP, as well as the proven benefits of early diagnosis and timely intervention to minimize the risk of severe visual loss, a joint statement outlining the principles of a screening program for ROP has been set forth:

- Screening for ROP should be performed in all infants with a birth weight at or above 1500 g or gestational age of 30 weeks or less (as defined by the attending neonatologist) and selected infants with a birth weight between 1500 and 2000 g or gestational age of more than 30 weeks with an unstable clinical course.
- In most cases, at least two examinations should be performed. One examination may suffice if it shows unequivocally that retinal vascularization is complete bilaterally. The first examination should be performed between 4 and 6 weeks of chronological (postnatal) age or between 31 and 33 weeks of postmenstrual age (PMA) (calculated as GA plus chronological age), whichever is later.
- Infants with immature retinas (no ROP) vascularized into zone II or III may be examined at 2-week intervals.
- Infants with type 2 prethreshold disease require weekly or twice weekly exams.
- Infants with type 1 prethreshold disease should be considered for peripheral laser ablation.

## ROLE OF TELEMEDICINE IN ROP SCREENING

The historical gold standard method for ROP screening has been bedside examination with binocular indirect ophthalmoscopy (BIO). However, a significant limitation of bedside examination is the subjectivity of the examiner’s impression of the BIO findings with its subsequent documentation. Several studies have shown a wide range of disagreement of ROP diagnosis and severity among healthcare professionals screening for ROP.<sup>33,34</sup> In the pivotal CRYO-ROP trial, there was disagreement between two unmasked, certified examiners as to whether threshold disease was present in 12% of eyes. Moreover, accurate documentation of retinal pathology in ROP is critical for longitudinal comparison and demonstration of sound clinical practice, especially in the complex medicolegal climate that surrounds ROP.

The feasibility of remote digital fundus imaging in screening for ROP was first demonstrated in 2000,<sup>35</sup> and since then numerous studies<sup>36</sup> clinical trials,<sup>37</sup> and live telemedicine programs<sup>38</sup> have validated the accuracy and sensitivity of “store-and-forward” telemedicine in effectively detecting treatment and/or referral-warranted ROP using contact wide-field digital cameras. These results are fairly consistent among different camera operators, including trained ophthalmologists,<sup>39,40</sup> trained neonatal personnel,<sup>41,42</sup> and ophthalmic photographers.<sup>40,43</sup> The latter is of great importance for communities with limited access to ROP providers and geographically restricted neonatal intensive care units and for connecting ROP screeners with experts for management of complex cases.

## DIFFERENTIAL DIAGNOSIS

In a premature infant of low BW with characteristic findings of immature retinal development, the diagnosis of ROP is generally straightforward. FEVR is the main masquerader that may mimic ROP in infancy. With its characteristic skin findings and gender predilection, incontinentia pigmenti is another pediatric retinal vasculopathy that shares similar clinical features with ROP. On the other hand, if a premature infant has not been screened or treated appropriately, the presenting finding may be leukocoria due to retrolental fibrous proliferation. In such infants, the differential diagnosis is broader and includes:

**Fig. 6.21.2** (A) **Stage 1.** The flat white border between avascular and vascular retina seen temporally is called a demarcation line. (B) **Stage 2.** The elevated mesenchymal ridge has height. Highly arborized blood vessels from the vascularized retina dive into the ridge. (C) **Stage 3.** Vessels on top of the ridge project into the vitreous cavity. This extraretinal proliferation carries with it a fibrovascular membrane. Note the opalescent avascular retina anterior to the ridge. Hemorrhage on the ridge is not uncommon. (D) **Stage 4.** Retinal detachment sparing the fovea. (E) **Stage 4B.** Detachment involves the fovea with an early retinal fold formation. (F) **Stage 5.** Depiction of an open anterior configuration secondary to fibrovascular proliferation that pulls the peripheral retina anteriorly.

**Fig. 6.21.3** (A) An example of moderate plus disease. Dilated retinal veins and tortuous arteries may be seen in the posterior pole. (B) Pre-plus disease. (C–D) Aggressive posterior retinopathy of prematurity.

- Retinoblastoma.
- Persistent fetal vasculature (formerly called persistence of primary hyperplastic vitreous; usually unilateral and associated with microphthalmia and prominent ciliary processes).
- Exudative retinal detachment (most commonly from Coats' disease; usually unilateral and more common in boys).
- Infectious causes such as endogenous endophthalmitis, toxocariasis, or toxoplasmosis (all of which may be diagnosed by appropriate microbiological and immunological testing).
- Coloboma of the optic disc or choroid.
- Cataract.
- Genetic syndromes, such as trisomy 13, Norrie's disease, and Warburg syndrome (all of which may be diagnosed by genetic testing and/or characteristic systemic physical findings).

## **PATHOLOGY**

Earlier histological studies demonstrated that the ridge in ROP consists of a larger anterior collection of spindle-shaped cells in the nerve fiber layer (the “vanguard”) and a variably present smaller posterior vascularized rear-guard.<sup>44</sup> These spindle-shaped cells are predominantly astrocyte precursors and, to a far lesser extent, mature astrocytes.<sup>45</sup> Stage 1 ROP is characterized by hyperplasia of the primitive spindle-shaped cells of the vanguard mesenchymal tissue at the demarcation line, whereas stage 2 consists of further hyperplasia of the spindle cells along with proliferation of the endothelial cells of the rear-guard mesenchymal tissue. In stage 3, extraretinal vascular tissue emanates from the ridge.<sup>44</sup> Proliferation of endothelial cells and small, thin-walled vessels occurs and represents abnormal angiogenesis. Equally important is the condensation of vitreous into sheets and

strands oriented anteriorly toward the equator of the lens. Vitreous tractional forces draw the retina anteriorly leading to foreshortening, folding, and subsequent retinal detachment.<sup>46</sup>

## **TREATMENT**

The goals of any acute ROP treatment is the abolishment of the angiogenic response driven by the avascular retina, which can be achieved by cryotherapy, laser photocoagulation, and pharmacological blockade of VEGF. Surgical intervention is reserved for the cicatricial stages of ROP leading to retinal traction, hemorrhage, and detachment.

## **ABLATION OF PERIPHERAL AVASCULAR RETINA**

Peripheral retinal ablation has been the mainstay of therapy for vasoproliferative retinopathy of prematurity dating back to the CRYO-ROP study. Cryotherapy has been employed to achieve peripheral retinal ablation for ROP since the 1970s<sup>29</sup> but has largely been supplanted by laser.<sup>47</sup> Indications for utilizing cryotherapy include poor fundus visibility, lack of laser availability, and physician's unfamiliarity with indirect laser techniques.

Laser photocoagulation has been shown to be at least as effective as<sup>48</sup>—if not more effective<sup>49</sup> than—cryotherapy for threshold disease.<sup>50</sup> In the largest prospective, randomized comparison of laser photocoagulation with cryotherapy (25 infants followed for at least 4 years), eyes treated with laser were significantly more likely to have visual acuity of 20/50 or better and were significantly less myopic.<sup>51,52</sup> The advantage of laser is greatest for eyes with zone I disease. Favorable anatomical results have been reported in 83%–85% of all eyes<sup>53,54</sup> versus only 25% of eyes with zone I disease treated with cryopexy.<sup>35</sup>

Advantages of laser photocoagulation over cryotherapy include ease of treatment, portability, and fewer systemic complications. Photocoagulation is delivered through a dilated pupil with a 20.00 D or 28.00 D lens. The endpoint is near-confluent ablation with burns spaced one-half burn width apart from the ora serrata up to (but not including) the ridge for 360°<sup>56</sup> (Fig. 6.21.3D). The retina should be inspected for skip areas, and the infant should be re-examined within 1 week. Persistent plus disease or fibrovascular proliferation are indications for additional treatment. Complications of laser treatment include anterior segment ischemia, cataract, high myopia, and burns of the cornea, iris, or tunica vasculosa lentis.<sup>57–59</sup>

The limitations of peripheral retinal ablation include the irreversible and extensive destruction of peripheral retina, concomitant reduction in visual fields, the laborious nature of the treatment, and the high level of training required to administer and monitor the treatment.

## ROLE OF ANTI-VEGF THERAPY IN ROP TREATMENT

The off-label use of anti-VEGF agents (bevacizumab or ranibizumab) in eyes with advanced ROP is supported by more than 50 case reports/case series<sup>60</sup> and one randomized, controlled clinical trial.<sup>61</sup> A systematic analysis<sup>62</sup> and an evidence-based meta-analysis<sup>63</sup> of VEGF inhibition as a treatment for ROP concluded that there is considerable variability in treatment indications, dosage, treatment timing, and treatment frequency; thus extrapolation of safe guidelines is challenging. In addition, although the BEAT-ROP study provided the first evidence in the context of a prospective, randomized controlled clinical trial of the prevailing concept that VEGF inhibition has a role in acute zone I ROP, it also raised significant questions, mostly due to a population bias of patients enrolled in the study, unusually high failure rate of laser treatment compared to ETROP standards, and higher number of deaths in the bevacizumab group (although the study was not powered for evaluation of safety).<sup>61</sup>

The dual role of VEGF in development and disease also makes employment of anti-VEGF therapy more challenging because the optimal dosing and choice of drug are still unknown. In the BEAT-ROP trial and the majority of published case series, a dose of 0.625 mg/0.025 mL was employed, which according to preclinical data delivers a dose of more than 10<sup>4</sup> as much anti-VEGF antibody as VEGF present in the vitreous of infants with ROP.<sup>12,64</sup> Indeed, a dose of bevacizumab as low as 0.031 mg has been shown to be effective in a recent phase 1 study for type 1 ROP.<sup>65</sup> It is also hoped that the RAINBOW study (RAnibizumab Compared With Laser Therapy for the Treatment of INfants BOrn Prematurely With Retinopathy of Prematurity; NCT02375971), which is an ongoing, phase 3, randomized, multicenter, prospective clinical trial that investigates the efficacy and safety of ranibizumab (Lucentis; Genentech, South San Francisco, CA) in infants with type 1 ROP compared with laser therapy, will provide better information on the dosing regimen (0.2 mg and 0.1 mg ranibizumab) as well. The latter has important implications given the systemic absorption of anti-VEGF agents and their potential impact on neurodevelopmental outcomes.<sup>66,67</sup>

In summary, the current available evidence for the follow-up, safety, and efficacy of anti-VEGF treatment is on a much lower level than the evidence for laser therapy, which has been established for more than four decades. Certainly there are advantages of anti-VEGF, such as ease of administration, fewer refractive errors compared to laser,<sup>68</sup> and allowance of centrifugal vascular retinal growth, but these await robust clinical trials

to be carefully evaluated under the scope of systemic safety and critical role of VEGF in retinal development. In the current clinical practice, however, anti-VEGF injections can be particularly helpful in the following scenarios:

- Treatment-naïve eyes with vascular congestion of the anterior segment precluding adequate visualization for laser treatment.
- Primary monotherapy (without adjuvant retinal ablation) for eyes with posterior or aggressive disease.<sup>69</sup>
- Infants unable to tolerate general anesthesia for intubation and laser treatment.

## SURGERY IN ROP TREATMENT

Although retinal ablation is effective in a majority of cases of ROP, some eyes will progress to retinal detachment (RD) at a mean of 41 weeks PMA after effective laser ablation.<sup>70</sup> ROP RD is most commonly tractional, originating at the ridge in a circumferential, purse-string pattern that draws the retina anteriorly and centrally. The surgical goal is interrupting the traction resulting from fibrous proliferation, and several tractional vectors must be addressed for surgical success (Fig. 6.21.4A–D).

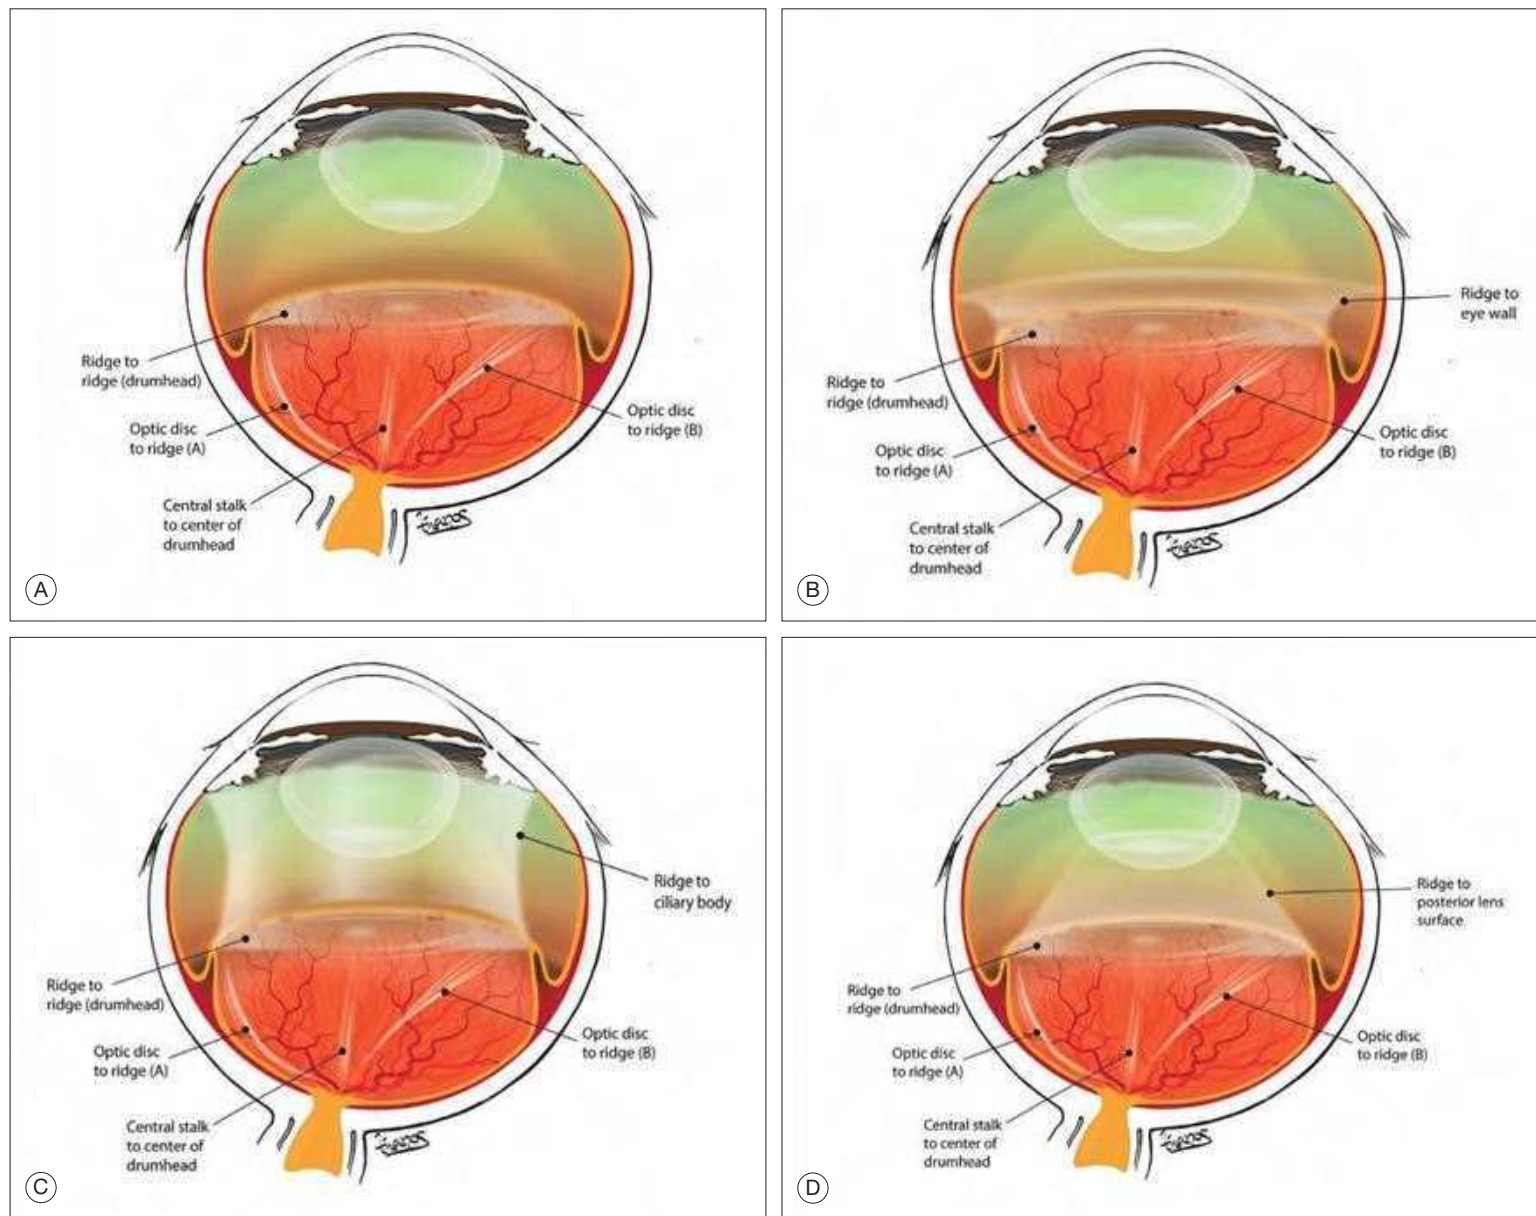

The goal of intervention for ROP-related RD varies with the severity of the detachment. The goal for extramacular retinal detachment (stage 4A ROP) is an undistorted or minimally distorted posterior pole, total retinal reattachment, and preservation of the lens and central fixation vision. Scleral buckling<sup>71,72</sup> and vitrectomy<sup>73</sup> have been used to manage stage 4A ROP. Disadvantages of scleral buckling for stage 4A ROP are the dramatic anisometropic myopia and the second intervention required for transection or removal so that the eye may continue to grow.<sup>74</sup> Lens-sparing vitrectomy can interrupt progression of ROP from stage 4A to stages 4B or 5 by directly addressing transvitreal traction resulting from fibrous proliferation and has become the method of choice.<sup>75,76</sup> Data from several centers dedicated to surgery for advanced ROP have shown that in experienced hands, lens-sparing vitrectomy allows primary retinal reattachment in 60%–90% of eyes with stage 4 ROP.<sup>73,77</sup> Visual results following vitrectomy for stage 4A can be very rewarding, with mean visions on the order of 20/60.<sup>78</sup>

Surgery for tractional RD involving the macula (stage 4B ROP) is performed to minimize retinal distortion and prevent total detachment (stage 5). The functional goal is ambulatory vision.<sup>79</sup> In earlier studies, visual outcome for retinal detachment beyond stage 4A was quite poor. More recent reports demonstrate that form-vision can be obtained by vitrectomy for stage 5 ROP.<sup>80,81</sup> Maximal recovery of vision following macula-off RD and interruption of visual development in infants may take years.

## LATE COMPLICATIONS OF ROP

Retinopathy of prematurity is a disease with lifelong ocular sequelae and adults with history of prematurity have increased prevalence of amblyopia, myopia, strabismus, early nuclear sclerotic cataract, and glaucoma.<sup>82</sup> Common retinal findings of regressed ROP include perivascular straightening, pigmentary changes, peripheral cicatricial changes, vascularization over a regressed ridge tissue, and lattice degeneration. Higher retinal complication rates after cataract surgery<sup>83,84</sup> and failure rates after retinal tears/detachment treatment in this patient population are attributable to an abnormal vitreoretinal interface, specifically the posterior border of the vitreous base, which demonstrates significant organization and tight adherence to the retina.<sup>85,86</sup>

**Fig. 6.21.4 Tractional Vectors Occurring in Retinopathy of Prematurity-Related Detachments.** The primary tractional vectors in retinopathy of prematurity related retinal detachments are ridge to ridge (drumhead) and optic disc to ridge (A), ridge to eye wall (B), ridge to ciliary body (C), and ridge to posterior lens surface (D).

# Diabetic Retinopathy

Jennifer I. Lim

# 6.22

**Definition:** Progressive dysfunction of the retinal vasculature caused by chronic hyperglycemia resulting in structural damage to the neural retina.

## Key Features

- Microaneurysms.
- Retinal hemorrhages.
- Retinal lipid exudates.
- Cotton-wool spots.
- Capillary nonperfusion.
- Macular edema.
- Neovascularization.

## Associated Features

- Vitreous hemorrhage.
- Retinal detachment.
- Neovascular glaucoma.
- Early onset cataract.
- Cranial nerve palsies.

## INTRODUCTION

Successful management of diabetic retinopathy requires not only local treatment (laser therapy, intravitreal pharmacotherapy, and vitrectomy) but also systemic control of hyperglycemia, blood pressure, and lipids. If fundus examinations are initiated before the development of significant retinopathy and repeated periodically—and if the recommendations of the Early Treatment Diabetic Retinopathy Study (ETDRS) and recent anti-vascular endothelial growth factor (VEGF) clinical trials results are applied in the management of diabetic macular edema or neovascularization—the risk of severe visual loss is less than 5%. However, diabetic retinopathy remains the number one cause of new blindness in most industrialized countries because of delays in seeking treatment. The vast majority of diabetic individuals who lose vision do so not because of an inability to treat their disease but due to a delay in seeking medical attention. In addition, in many countries, the incidence of diabetes is increasing dramatically.

## EPIDEMIOLOGY

Duration of retinopathy is most closely associated with the incidence of diabetic retinopathy and remains the best predictor of diabetic retinopathy.<sup>1</sup> The first five years of type 1 diabetes has a very low risk of retinopathy. However, 27% of those who have had diabetes for 5–10 years and 71%–90% of those who have had diabetes for longer than 10 years have diabetic retinopathy.<sup>2</sup> After 20–30 years, the incidence rises to 95%, and about 30%–50% of these patients have proliferative diabetic retinopathy (PDR).

Yanko et al.<sup>3</sup> found that the prevalence of retinopathy 11–13 years after the onset of type 2 diabetes was 23%; after 16 or more years, it was 60%; and 11 or more years after the onset, 3% of the patients had PDR. Klein et al.<sup>2</sup> reported that 10 years after the diagnosis of type 2 diabetes, 67% of patients had retinopathy and 10% had PDR.

The duration of diabetes after the onset of puberty appears to be most important. For example, the risk of retinopathy is roughly the same for two 25-year-old patients, one of whom developed diabetes at the age of 6 and the other at the age of 12 years.<sup>4</sup> The risk of retinopathy in children diagnosed prior to the age of 2 years has a negligible risk of retinopathy for the first 10 years.<sup>5</sup>

The Diabetes Control and Complications Trial (DCCT) showed that type 1 diabetics who closely monitored their blood glucose via tight control (four measurements per day = tight control) had a 76% reduction in the rate of development of any retinopathy (primary prevention cohort) and a 54% reduction in progression of established retinopathy (secondary intervention cohort) as compared with the conventional treatment group (one measurement per day).<sup>6</sup> For advanced retinopathy, however, even the most rigorous control of blood glucose may not prevent progression. The DCCT was halted early after 6.5 years when the benefit of tight control was deemed unlikely to be reversed with time. Most of the participants were followed in the Epidemiology of Diabetes Interventions and Complications (EDIC) study. The EDIC study showed continued benefit for the former tight control group over the former conventional treatment group, despite normalization of glucose control even after 7 years of follow-up.<sup>7</sup> The value of intensive treatment has also been demonstrated for type 2 diabetes. The United Kingdom Prospective Diabetes Study (UKPDS) revealed a 21% reduction in the 1-year rate of progression of retinopathy.<sup>8</sup> The DCCT has shown that for every 1% decrease in the hemoglobin A1C (HbA1C) level, the incidence of diabetic retinopathy decreases 28%.<sup>9</sup>

It is important to realize that many patients with diabetes are unaware of their diabetic retinopathy. A Joslin Diabetes Center study on self-awareness of diabetic retinopathy found that 83% of patients with diabetic retinopathy and 78% of those with vision-threatening disease were unaware they had diabetic retinopathy at their first visit. Communication and education of the patient are very important.<sup>10</sup> The Diabetic Retinopathy Clinical Research Network (DRCR) evaluated the effect on retinopathy of educating the diabetic patient about their HbA1C and blood pressure levels at their regular retinal examination visits.<sup>11</sup> Despite physician-initiated discussion of in-office measurements of HbA1C and blood pressure readings with patients at their scheduled visits, the HbA1C levels did not significantly change from baseline. This suggests that more frequent and/or intensive intervention is needed than checking of these levels and discussing the results during a routine retinal evaluation. Renal disease, as evidenced by proteinuria, elevated blood urea nitrogen levels, elevated blood creatinine levels, and even microalbuminuria, is an excellent predictor of the presence of coexisting retinopathy.<sup>1,12</sup> Among patients with symptomatic retinopathy, 35% have proteinuria, elevated blood urea nitrogen values, or elevated creatinine levels. Systemic hypertension is another independent risk factor for diabetic retinopathy. The UKPDS demonstrated that tighter blood pressure control significantly reduced the progression of diabetic retinopathy.<sup>13</sup>

In pregnant diabetic women without retinopathy, the risk of developing nonproliferative diabetic retinopathy (NPDR) is about 10%. In contrast, those with NPDR and systemic hypertension at the onset of pregnancy—or those who develop systemic hypertension—are likely to show progression, with increased hemorrhages, cotton-wool spots, and macular edema.<sup>8</sup> Fortunately, there is usually some regression after delivery. About 4% of pregnant women with NPDR progress to PDR. Those with untreated PDR at the onset of pregnancy frequently do poorly unless they are treated with panretinal photocoagulation (PRP). Previously treated PDR usually does not worsen during pregnancy. Women who begin pregnancy with poorly controlled diabetes who are suddenly brought under strict control frequently have severe deterioration of their retinopathy and do not always recover after delivery.<sup>14</sup> It is very important to monitor pregnant patients carefully and closely, with some clinicians advocating quarterly examinations. Anti-VEGF treatment has not been studied in pregnant women. Laser or other non-anti-VEGF treatment is recommended. In addition, fluorescein dye is known to cross the placenta and is also excreted in breast milk for up to 72 hours.<sup>15</sup>

Some drugs have been implicated in worsening retinopathy and in particular diabetic macular edema (DME). Glitazones are associated with an

increased risk of worsening of DME.<sup>16</sup> A study of 170 000 patients in the Kaiser Permanente database showed that patients treated with glitazones had a significantly higher risk of developing DME (odds ratio 2.6, 95% confidence interval 2.4–3.0) in a univariate analysis.<sup>17</sup> After adjusting for confounding factors, the odds ratio was 1.6, 95% confidence interval 1.4–1.8. Some clinical trials have shown a higher risk of DME in patients taking insulin and glitazones (Actos package insert. Deerfield IL: Takeda Pharmaceutical America, Inc, 2011). It is therefore important to review a patient's drug history when evaluating diabetic patients with macular edema. The glitazone rosiglitazone, however, was shown to lower the risk of progression to PDR and to have similar rates of DME as controls at 3 years.<sup>18</sup> In The Health Improvement Network (THIN) database, a large retrospective cohort study of 103 368 patients with type II diabetes mellitus and no DME at baseline, an increased risk of DME was found at both 1 and 10 years for users of thiazolidinediones compared to nonusers. The adjusted odds ratio was 2.3 at 1 year and the adjusted hazard ratio was 2.3 at 10 years.<sup>19</sup>

## PATHOGENESIS

The final metabolic pathway that causes diabetic retinopathy is unknown. There are several theories that are not mutually exclusive.

### Aldose Reductase

Aldose reductase converts sugars into their alcohols. For example, glucose is converted to sorbitol and galactose is converted to galactitol. However, sorbitol and galactitol cannot easily diffuse out of cells, causing increased intracellular concentration. Osmotic forces then cause water to diffuse into the cell. The resultant damage to lens epithelial cells, which have a high concentration of aldose reductase, is responsible for the cataract seen in children.<sup>20</sup> Because aldose reductase is also found in high concentration in retinal pericytes and Schwann cells, some investigators suggest that diabetic retinopathy and neuropathy may be caused by aldose reductase-mediated damage. Despite these theoretical benefits, clinical trials have thus far failed to show a reduction in the incidence of diabetic retinopathy or of neuropathy by aldose reductase inhibitors, possibly because an effective aldose reductase inhibitor with few systemic side effects has yet to be developed.<sup>19</sup>

### Vasoproliferative Factors

The retina and retinal pigment epithelium release vasoproliferative factors, such as VEGF, which induce neovascularization. VEGF has a direct role in the proliferative retinal vascular abnormalities that are found in diabetes. Animal models have demonstrated that VEGF expression correlates with the development and regression of neovascularization.<sup>21</sup> The concentration of VEGF in aqueous and vitreous directly correlates with the severity of retinopathy.<sup>22</sup> VEGF is a potent vasopermeability factor and is responsible for DME.<sup>23</sup> Several randomized controlled clinical trials have shown efficacy of anti-VEGF treatments for DME. There are other vasoactive cytokines released in diabetic eyes. These include tissue growth factor beta and connective tissue growth factor. The inflammatory component results from macrophage and complement activation. Extensive, dense deposition of C5b-9 as well as vitronectin were found in the connective matrix of the choriocapillaris. It is believed that complement activation results in increased neutrophils, which then cause endothelial damage. Lipids and proteins leak out of the capillaries. Extracellular matrix deposition may be triggered by the complement cascade's effects on neighboring cells and result in thickened choriocapillaris and Bruch's membrane.<sup>24</sup> Inflammation thus plays a role in macular edema and diabetic retinopathy. It is believed that long-standing DME may have more of an inflammatory component and be more responsive to corticosteroids, which are also antiangiogenic.<sup>25</sup>

### Platelets and Blood Viscosity

Diabetes is associated with abnormalities of platelet function. It has been postulated that platelet abnormalities or alterations in blood viscosity in diabetics may contribute to diabetic retinopathy by causing focal capillary occlusion and focal areas of ischemia in the retina.

## OCULAR MANIFESTATIONS

The earliest stage of diabetic retinopathy is NPDR. In some patients, there is progression to proliferative retinopathy PDR. The incidence of more

**Fig. 6.22.1 Nonproliferative Diabetic Retinopathy With Microaneurysms.**

(A) Small dot hemorrhages, microaneurysms, hard (lipid) exudates, circinate retinopathy, an intraretinal microvascular abnormality, and macular edema. (B) Fluorescein angiography of the eye shown in A. Microaneurysms are seen as multiple dots of hyperfluorescence, but the dot hemorrhages do not fluoresce. The foveal avascular zone is minimally enlarged.

advanced levels of retinopathy increases based on duration of disease and glycemic control.

### Early Nonproliferative Diabetic Retinopathy

Microaneurysms are the first ophthalmoscopically detectable change in diabetic retinopathy and are considered the hallmark of NPDR (Fig. 6.22.1A). They are seen as small red dots in the middle retinal layers, typically in the macula. When the wall of a capillary or microaneurysm is weakened enough, it may rupture, giving rise to an intraretinal hemorrhage. If the hemorrhage is deep (i.e., in the inner nuclear layer or outer plexiform layer), it usually is round or oval ("dot or blot") (see Fig. 6.22.1A). It is very difficult to distinguish a small dot hemorrhage from a microaneurysm by ophthalmoscopy. Fluorescein angiography helps to distinguish patent (and not one filled with clotted blood) microaneurysms because they leak dye (see Fig. 6.22.1B). If the hemorrhage is superficial, in the nerve fiber layer, it takes a flame or splinter shape indistinguishable from a hemorrhage seen in hypertensive retinopathy (Figs. 6.22.2 and 6.22.3). Diabetics who have normal blood pressure may have multiple splinter hemorrhages. Nevertheless, the presence of numerous splinter hemorrhages in a diabetic patient should prompt a blood pressure check.

DME (see Fig. 6.22.1A) represents the leading cause of legal blindness in diabetics. The intercellular fluid comes from leaking microaneurysms or from diffuse capillary incompetence. Clinically, DME is best detected by slit-lamp biomicroscopy with a contact macular lens, although noncontact macular lenses can be used. The edema causes separation of cells, resulting in scattering of light by the multiple interfaces. This decreases the retina's translucency such that the normal retinal pigment epithelial and choroidal background pattern is blurred (see Fig. 6.22.1A). Pockets of fluid in the outer plexiform layer, if large enough, can be seen as cystoid

**Fig. 6.22.2 Nonproliferative Retinopathy With Some Blot Hemorrhages, Splinter Hemorrhages, and Cotton-Wool Spots.**

**Fig. 6.22.3 Nonproliferative Retinopathy.** (A) With soft exudates. (B) Fluorescein angiography shows capillary nonperfusion in the area of the superior cotton-wool spot and a larger area just inferonasal to the foveal avascular zone.

macular edema (CME). Usually CME is seen in eyes that have other signs of severe NPDR. In rare cases, CME is due to generalized diffuse leakage from the entire capillary network and can be seen in eyes with very few other signs of diabetic retinopathy.

If the leakage of fluid is severe enough, lipid may accumulate in the retina (see Fig. 6.22.1A); again, the outer plexiform layer is first to be affected. In some cases, lipid is scattered through the macula. In others, it accumulates in a ring around a group of leaking microaneurysms or around microaneurysms surrounding an area of capillary nonperfusion. This pattern is called circinate retinopathy (see Fig. 6.22.1A).

The application of optical coherence tomography (OCT) to management of DME has been very useful. The degree of DME and response to therapy can be quantified on OCT. Specifically, the central subfield thickness (CST)

**Fig. 6.22.4 Severe Nonproliferative Retinopathy.** (A) With cotton-wool spots, intraretinal microvascular abnormalities, and venous beading. (B) Fluorescein angiography shows severe capillary nonperfusion.

can be used to follow a patient's response to treatment of DME. In addition, the OCT presents qualitative information such as the presence of cysts, hard exudates, and degree of inner or outer retinal or external limiting membrane disruption and subretinal fluid. These findings are useful in following a patient's response to therapy.

In eyes treated with anti-VEGFs, the presence of disorganization of retinal inner layers (DRIL) has been associated with poorer visual acuity outcomes. The length of DRIL was associated with subsequent vision. The change in DRIL was associated with change in visual acuity (VA), with resolution of DRIL having the best VA. Early change in the extent of DRIL is inversely predictive of subsequent changes in visual acuity.<sup>26,27</sup>

### Advanced Nonproliferative Diabetic Retinopathy

In advanced NPDR, signs of increasing inner retinal hypoxia appear, such as multiple retinal hemorrhages, cotton-wool spots (see Fig. 6.22.3), venous beading and vascular loops (Fig. 6.22.4), intraretinal microvascular abnormalities (IRMAs) (see Figs. 6.22.1A and 6.22.4), and large areas of capillary nonperfusion seen on fluorescein angiography.

Cotton-wool spots, also called soft exudates or nerve fiber infarcts, result from ischemia, not exudation. Local ischemia causes effective obstruction of axoplasmic flow in the normally transparent nerve fiber layer, and the subsequent swelling of the nerve fibers gives cotton-wool spots their characteristic white fluffy appearance. Fluorescein angiography shows lack of capillary perfusion in the area corresponding to a cotton-wool spot. Microaneurysms frequently surround the hypoxic area (see Fig. 6.22.3).

Venous beading (see Fig. 6.22.4) is an important sign of sluggish retinal circulation. Venous loops are nearly always adjacent to large areas of capillary nonperfusion. IRMAs are dilated capillaries that seem to function as collateral channels and are frequently difficult to differentiate from surface retinal neovascularization. Fluorescein dye, however, does not leak from IRMAs but leaks profusely from neovascularization. Capillary hypoperfusion often surrounds IRMA (see Fig. 6.22.4).

**Fig. 6.22.5** Approximately One-Half the Disc Area Shows Neovascularization of the Disc and Initial, Incomplete Panretinal Photocoagulation.

The ETDRS found that IRMAs, multiple retinal hemorrhages, venous beading and loops, widespread capillary nonperfusion, and widespread leakage on fluorescein angiography were all significant risk factors for the development of PDR. Interestingly, cotton-wool spots were not.<sup>28</sup>

### Proliferative Diabetic Retinopathy

Although the macular edema, exudates, and capillary occlusions seen in NPDR often cause legal blindness, affected patients usually maintain at least ambulatory vision. PDR, on the other hand, may result in severe vitreous hemorrhage or retinal detachment, with hand-movements vision or worse. Approximately 50% of patients with very severe NPDR progress to PDR within 1 year.<sup>29</sup> Proliferative vessels usually arise from retinal veins and often begin as a collection of multiple fine vessels. When they arise on or within 1 disc diameter of the optic nerve they are referred to as NVD (neovascularization of the disc, Figs. 6.22.5 and 6.22.6). When they arise further than 1 disc diameter away, they are called NVE (neovascularization elsewhere) (see Fig. 6.22.6B). Unlike normal retinal vessels, NVD and NVE leak fluorescein into the vitreous.

Once the stimulus for growth of new vessels is present, the path of subsequent growth taken by neovascularization is along the route of least resistance. For example, the absence of a true internal limiting membrane on the disc could explain the prevalence of new vessels at that location. Also, neovascularization seems to grow more easily on a preformed connective tissue framework. Thus, a shallowly detached posterior vitreous face is a frequent site of growth of new vessels.

The new vessels usually progress through a stage of further proliferation, with associated connective tissue formation. As PDR progresses, the fibrous component becomes more prominent, with the fibrotic tissue being either vascular or avascular. The fibrovascular variety usually is found in association with vessels that extend into the vitreous cavity or with abnormal new vessels on the surface of the retina or disc. The avascular variety usually results from organization or thickening of the posterior hyaloid face. Vitreous traction is transmitted to the retina along these proliferations and may lead to traction retinal detachment.

NVE nearly always grows toward and into zones of retinal ischemia until posterior vitreous detachment occurs (see Fig. 6.22.6). Then the vessels are lifted into the vitreous cavity. The end stage is characterized by regression of the vascular tissue. Sometimes there may be contraction of the connective tissue components, development of subhyaloid bands, thickening of the posterior vitreous face, and the appearance of retinoschisis, retinal detachment, or formation of retinal breaks.

Posterior vitreous detachment in diabetics is characterized by a slow, overall shrinkage of the entire formed vitreous rather than by the formation of cavities caused by vitreous destruction. Davis et al.<sup>30</sup> have stressed the role of the contracting vitreous in the production of vitreous hemorrhage, retinal breaks, and retinal detachment. Neovascular vessels do not “grow” forward into the vitreous cavity but are pulled into the vitreous by the contracting vitreous to which they adhere. Confirmation of the importance of the vitreous in the development and progression of PDR comes from the long-term follow-up of eyes that have undergone successful vitrectomy in

**Fig. 6.22.6** Neovascularization. (A) Neovascularization of the disc with some fibrous proliferation. (B) Neovascularization elsewhere.

which neovascularization shrinks, fluorescein leakage decreases, and new areas of neovascularization rarely arise.

It has long been assumed that sudden vitreous contractions tear the fragile new vessels, causing vitreous hemorrhage. However, the majority of diabetic vitreous hemorrhages occur during sleep, possibly because of an increase in blood pressure secondary to early morning hypoglycemia or to rapid eye movement sleep. Because so few hemorrhages occur during exercise, it is not necessary to restrict the activity of patients with PDR. When a hemorrhage occurs, if the erythrocytes are behind the posterior vitreous face, they usually quickly settle to the bottom of the eye and are absorbed. However, when erythrocytes break into the vitreous body, they adhere to the gel, and clearing may take months or years.

A large superficial hemorrhage may separate the internal limiting membrane from the rest of the retina. Such hemorrhages usually are round or oval but also may be boat shaped. The blood may remain confined between the internal limiting membrane and the rest of the retina for weeks or months before breaking into the vitreous. Subinternal limiting membrane hemorrhages were formerly thought to occur between the internal limiting membrane and the cortical vitreous and were called subhyaloid or preretinal hemorrhages. It is now felt that true subhyaloid hemorrhages probably are quite rare. Tight subinternal limiting membrane hemorrhages are dangerous because they may progress rapidly to traction retinal detachment.

As the vitreous contracts, it may pull on the optic disc, causing traction striae involving the macular area or actually drag the macula itself, both of which contribute to decreased visual acuity.<sup>31</sup>

Two types of diabetic retinal detachments occur, those that are caused by traction alone (nonrhegmatogenous) and those caused by retinal break formation (rhegmatogenous). Characteristics of nonrhegmatogenous (traction) detachment in PDR include:

- The detached retina usually is confined to the posterior fundus and infrequently extends more than two thirds of the distance to the equator.

- The detached retina has a taut and shiny surface.
- The detached retina is concave toward the pupil.
- No shifting of subretinal fluid occurs.

Occasionally, a spontaneous decrease in the extent of a traction detachment may occur, but this is the exception rather than the rule. Traction on the retina also may cause focal areas of retinoschisis, which may be difficult to distinguish from full-thickness retinal detachment. In retinoschisis the elevated layer is thinner and more translucent.

When a detachment is rhegmatogenous, the borders of the elevated retina usually extend to the ora serrata. The retinal surface is dull and grayish and undulates because of retinal mobility due to shifting of subretinal fluid. Retinal breaks are usually in the posterior pole near areas of fibrovascular change. The breaks are oval in shape and appear to be partly the result of tangential traction from the proliferative tissue, as well as being due to vitreous traction. Determination of the location of retinal holes may be complicated by many factors, particularly poor dilatation of the pupil, lens opacity, increased vitreous turbidity, vitreous hemorrhage, intraretinal hemorrhage, and obscuration of the breaks by overlying proliferative tissue.

## Other Ocular Complications of Diabetes Mellitus

### Cornea

Corneal sensitivity is decreased in proportion to both the duration of the disease and the severity of the retinopathy.<sup>32</sup> Corneal abrasions are more common in people with diabetes, presumably because adhesion between the basement membrane of the corneal epithelium and the corneal stroma is not as firm as that found in normal corneas. Following vitrectomy, recurrent corneal erosion, striate keratopathy, and corneal edema are more common in diabetics than in nondiabetics.<sup>33</sup>

### Glaucoma

The relationship between diabetes and primary open-angle glaucoma is unclear. Some population-based studies have found an association<sup>34</sup> but others have not.<sup>35</sup>

Neovascularization of the iris (NVI) usually is seen only in diabetics who have PDR. PRP not only has protective value against NVI, it also is an effective treatment against established NVI.<sup>36</sup> If the media are clear, PRP should be performed prior to any other treatment for NVI, even in advanced cases.<sup>28</sup> If the media are too cloudy for PRP, transscleral laser or peripheral retinal cryoablation are alternative means of treatment (see later in this chapter). The presence of rubeotic glaucoma is a poor prognostic indicator for visual acuity and for life expectancy.<sup>37</sup> Anti-VEGF therapy is also used as an adjunctive treatment in eyes with NVI.

### Lens

The risk of cataract is 2–4 times greater in diabetics than in nondiabetics and may be 15–25 times greater in diabetics under 40 years old.<sup>38</sup>

Patients with diabetes mellitus who have no retinopathy have excellent results from cataract surgery, with 90%–95% having a final visual acuity of 20/40 or better, but chronic CME is about 14 times more common in diabetics than in nondiabetics.<sup>39</sup> The best-known predictor of postoperative success is the preoperative severity of retinopathy.<sup>40</sup> It was hoped that modern surgery, which leaves an intact posterior capsule, would protect the eye from NVI by reducing the diffusion of vasoproliferative factors into the anterior chamber, but several studies have shown that it does not. Furthermore, a neodymium-aluminum-garnet (Nd:YAG) laser capsulotomy does not increase the risk.<sup>32</sup> Other anterior segment complications that are more common in diabetics than in nondiabetics are pupillary block, posterior synechiae, pigmented precipitates on the implant, and severe iritis.<sup>39</sup>

Posterior segment complications of cataract surgery include macular edema, PDR,<sup>41</sup> vitreous hemorrhage,<sup>42</sup> and traction retinal detachment. Unlike prior reports, recent reports suggest that modern uncomplicated cataract surgery may not accelerate progression of diabetic retinopathy in type 2 diabetics with NPDR.<sup>43</sup> Caution should be observed when considering cataract surgery in patients who have diabetic retinopathy, but up to 70% of these patients can attain a final visual acuity of 20/40 or better.<sup>44</sup> In a pilot observational study of eyes with baseline DME at the time of cataract surgery, the DRCR showed that 32% improved four lines and 10% worsened at least two lines by week 16. The study was limited by small enrollment and concluded that it was unlikely that an adequate sample could be recruited within a reasonable time to pursue an interventional trial for eyes with DME in the setting of cataract surgery.<sup>45</sup> For patients without macular edema at the time of cataract surgery, the DRCR found

that preoperative noncentral DME or a history of DME treatment may increase the risk of developing central-involved DME 16 weeks after cataract extraction. In addition, visual outcomes were good, with over 85% achieving 20/40 or better visual acuity. However, this was achieved less often in eyes that developed central-involved ME (67%), although these eyes had a lower mean baseline VA (Snellen equivalent 20/63) than eyes that did not develop central-involved ME (Snellen equivalent 20/50).<sup>46</sup>

Cataract surgery in patients with active PDR often results in poorer postoperative visual outcome because of the high risk of both anterior and posterior segment complications. In one series, no patient with active PDR or preproliferative diabetic retinopathy achieved better than 20/80. Most experts recommend aggressive preoperative PRP.<sup>39,40</sup>

## Optic Neuropathy

As demonstrated by increased latency and decreased amplitude of the visual evoked potential, many diabetic patients without retinopathy have subclinical optic neuropathy. They have an increased risk for anterior ischemic optic neuropathy. In addition, diabetics are susceptible to diabetic papillopathy, which is characterized by acute disc edema without the pale swelling of anterior ischemic optic neuropathy. It is bilateral in one-half of cases and may not show an afferent pupillary defect.<sup>47</sup> Macular edema is a common concurrent finding and is the most common cause of failure of visual recovery in these patients.<sup>47</sup> Visual fields may be normal or show an enlarged blind spot or other nerve fiber defects. The prognosis is excellent, with most patients recovering to 20/50 or better.

## Cranial Neuropathy

Extraocular muscle palsies may occur in diabetics secondary to neuropathy involving the third, fourth, or sixth cranial nerves. The mechanism is believed to be a localized demyelination of the nerve secondary to focal ischemia. Pain may or may not be experienced, and not infrequently extraocular muscle palsy may be the initial clue to a latent diabetic condition. Recovery of extraocular muscle function in diabetic cranial nerve palsies generally takes place within 1–3 months.<sup>48</sup> When the third cranial nerve is involved, pupillary function is usually normal. This pupillary sparing in diabetic third cranial nerve palsy is an important diagnostic feature, helping to distinguish it from an intracranial tumor or aneurysm.

## DIAGNOSIS AND ANCILLARY TESTING

In nearly all instances, diabetic retinopathy is diagnosed easily via ophthalmoscopic examination. The hallmark lesions are microaneurysms, which usually develop in the posterior pole. Without microaneurysms, the diagnosis of diabetic retinopathy is in doubt. Fasting blood sugar testing, a glucose tolerance test, and HbA1C determinations all can be used to confirm the presence of systemic hyperglycemia.

Intravenous fluorescein angiography is a widely administered ancillary test and is helpful to assess the severity of diabetic retinopathy, to determine sites of leakage in macular edema, to judge the extent of capillary nonperfusion, and to confirm neovascularization. It is a useful preoperative test to evaluate the extent of retinopathy in patients who are to undergo cataract surgery and have media opacity. OCT angiography is being increasingly used as a noninvasive test in diabetic retinopathy to visualize capillary nonperfusion and neovascularization. OCT is widely used to assess and follow macular edema.

## DIFFERENTIAL DIAGNOSIS

The differential diagnosis is listed in [Box 6.22.1](#).

## PATHOLOGY

The earliest histopathological abnormalities in diabetic retinopathy are thickening of the capillary basement membrane and pericyte dropout. Microaneurysms begin as a dilatation in the capillary wall in areas where pericytes are absent; microaneurysms initially are thin walled. Later, endothelial cells proliferate and deposit layers of basement membrane material around themselves. Fibrin may accumulate within the aneurysm, and the lumen of the microaneurysm may become occluded ([Fig. 6.22.7](#)). In early cases, microaneurysms are present mostly on the venous side of the capillaries, but later they are also seen on the arterial side. Despite the multiple layers of basement membrane, they are permeable to water and large molecules, resulting in water and lipid accumulation in the retina. Because

**Fig. 6.22.7 Microaneurysms, Pericyte Dropout, and Acellular Capillaries Are Seen.**

### BOX 6.22.1 Differential Diagnosis of Diabetic Retinopathy

- Radiation retinopathy
- Hypertensive retinopathy
- Retinal venous obstruction (central retinal vein occlusion [CRVO], branch retinal vein occlusion [BRVO])
- The ocular ischemic syndrome
- Anemia
- Leukemia
- Coats' disease
- Idiopathic juxtafoveal retinal telangiectasia
- Sickle cell retinopathy

fluorescein passes easily through them, many more microaneurysms are seen on fluorescein angiography than on ophthalmoscopy (see Figs. 6.22.1 and 6.22.3).

## TREATMENT

### Medical Therapy

#### Antiplatelet Therapy

The ETDRS reported that aspirin 650 mg daily does not influence the progression of retinopathy, affect visual acuity, or influence the incidence of vitreous hemorrhages. However, there was a significant decrease in cardiovascular morbidity in the aspirin-treated group compared with the placebo cohort.<sup>49</sup> Clopidogrel and ticlopidine, like aspirin, inhibit adenosine diphosphate-induced platelet aggregation. They have been shown to decrease the risk of stroke in patients with transient ischemic attacks, but there is no clear evidence showing an impact on diabetic retinopathy.

#### Antihypertensive Agents

The Hypertension in Diabetes Study, part of the United Kingdom Prospective Diabetes Study (UKPDS), evaluated the effect of blood pressure control on the progression of diabetic retinopathy. Patients were treated with angiotensin-converting enzyme inhibitors (ACEIs) or beta-blockers to achieve “tight” control of blood pressure (<150/85 mm Hg) or “less tight” control (<180/105 mm Hg). The group with better blood pressure control had a 37% risk reduction in microvascular changes. There was no difference in effect between the two agents used. Lisinopril, an ACEI, has also been shown to decrease the progression of NPDR and PDR in normotensive diabetics. The patients in this study with the better glycemic control benefited more from lisinopril.<sup>50</sup>

#### Antiangiogenesis Agents

The discovery that VEGF plays a critical role in the initiation of diabetic neovascularization and an important role in DME has revolutionized management of these complications of diabetes. Several pharmacological inhibitors of angiogenesis have been shown to be beneficial in the therapy of center-involving DME.<sup>51–67</sup> These include:

- Pegaptanib sodium, a VEGF aptamer (Macugen, Eyetech Pharmaceuticals, NY).<sup>53–56</sup>
- Ranibizumab (Lucentis, Genentech).<sup>55–61</sup>
- Bevacizumab (Avastin, Genentech).<sup>63,64</sup>
- Aflibercept (Eylea, Regeneron).<sup>65–67</sup>

All four anti-VEGF agents improve visual acuity and promote normalization of the macular architecture in most eyes with DME. Because of their superior beneficial effect compared to laser and corticosteroids, with a relatively good safety profile, anti-VEGF therapy is now considered primary treatment of fovea-involving DME in most eyes.

The major problems with anti-VEGF therapy are cost and frequency of administration. In addition, the risk of endophthalmitis with anti-VEGF therapy in diabetics appears to be greater than with other ophthalmic conditions (e.g., neovascular age-related macular degeneration, retinal venous occlusion), with several studies suggesting the long-term incidence may approach 1%.<sup>51</sup> In current clinical practice, pegaptanib is not as widely used, as the other agents appear to be more efficacious.<sup>51,52</sup> The DRCR Protocol T compared the visual and anatomical outcomes of bevacizumab, ranibizumab, and aflibercept for treatment of diabetic macular edema in patients with 20/32–20/320 visual acuity.<sup>55</sup> All three drugs did result in some improvement in visual acuity and reduction of edema by OCT. There were 9–10 treatments given in the first year for all three drugs. Overall, mean change in visual acuity was best for aflibercept (13 letters) which was greater than ranibizumab (11 letters,  $p = 0.034$ ) or bevacizumab (10 letters,  $p < 0.001$ ). For visual acuities better than 20/50, there was no significant difference in the visual or anatomic outcomes. However, for visual acuities of 20/50 or worse, aflibercept resulted in a mean gain of 19 letters versus 14 letters for ranibizumab ( $p = 0.0031$ ) or 12 letters for bevacizumab ( $p < 0.001$ ). More eyes gained 15 or more letters with aflibercept (67%) than ranibizumab (50%,  $p < 0.001$ ) or bevacizumab (41%,  $p = 0.0078$ ). There were no significant differences between the drugs in terms of percentage of eyes that lost 10 or more letters or 15 or more letters from baseline. Both ranibizumab and aflibercept resulted in significantly greater reductions in mean CST than bevacizumab. No significant differences in safety were found among the three drugs.

The best dosing regimen for the anti-VEGF remains controversial. It is generally agreed that monthly injections are indicated until the fluid has resolved or until no further improvement occurs, but once that point has been reached, it remains unclear whether further “mandated” monthly injections or long-term monthly injections versus a switch to an as-needed protocol is best. For those clinicians choosing to combine anti-VEGF therapy with focal laser, the optimal timing of the laser and anti-VEGF therapy is not as yet determined.<sup>55–61</sup> However, most studies support delayed laser photocoagulation, usually at about 6 months after initiating anti-VEGF therapy. With respect to the role of anti-VEGF therapy combined with immediate or deferred focal laser, the DRCR Protocol J<sup>55,56</sup> showed that ranibizumab with deferred ( $\geq 24$  weeks) laser is more efficacious than focal laser alone, intravitreal ranibizumab plus prompt (within 3–10 days of injection) focal laser, triamcinolone acetate plus prompt laser, or sham plus prompt focal laser treatment. Eyes treated with ranibizumab plus either prompt or deferred focal laser had better visual acuity outcomes than eyes treated with triamcinolone plus prompt laser or sham plus prompt laser. Interestingly, reductions in OCT central subfield thickness were similar between the ranibizumab and triamcinolone groups, suggesting the visual benefits of intravitreal corticosteroids may be tempered by their side effects: cataract and elevated intraocular pressure (IOP). Indeed, for pseudophakic eyes, ranibizumab and triamcinolone groups had similar outcomes. The rate of endophthalmitis was 0.8% in the ranibizumab groups versus none in the corticosteroid group or laser alone eyes.<sup>55–57</sup>

#### Bevacizumab

Bevacizumab is in wide usage for treatment of DME. While not studied as rigorously as the other anti-VEGFs, the cost differential favors it so greatly, that for many clinicians it is the first line therapy. The best data on this drug comes from the DRCR Study Protocol T (see earlier).<sup>55</sup> In addition, the Bevacizumab or Laser Therapy (BOLT) Study<sup>63</sup> showed that bevacizumab had superior visual outcomes (20/50 Snellen equivalent) in the 80 enrolled patients compared to laser 54.8 (20/80) at 2 years. The mean change in visual acuity was a gain of 8.6 letters for bevacizumab versus a mean loss of 0.5 letters for laser arm eyes. Forty-nine percent of patients gained 10 or more letters ( $p = 0.001$ ), and 32% gained at least 15 letters ( $p = 0.004$ ) for bevacizumab versus 7% and 4% for laser eyes. The median number of treatments over 24 months was 13 for bevacizumab

and four for laser. A large retrospective study of bevacizumab for DME was performed by the Pan-American Collaborative Retina Study Group (PACORES).<sup>64</sup> This group showed that stability or improvement of visual acuity occurred with 1.25 mg or 2.5 mg bevacizumab. No difference was seen between the two doses. The mean vision gained was 2.4 lines at 24 months for both groups.

### Pegaptanib

Pegaptanib sodium (Macugen), a selective VEGF-165 aptamer, was the first anti-VEGF agent used in DME.<sup>51,52</sup> Although pegaptanib-treated eyes had slightly better visual acuity outcomes and reduction of retinal edema by OCT as compared with sham-treated eyes, the results were not clinically convincing enough to change the standard of care. In the phase 2 macular edema study, a small subset of eyes also had PDR. The PDR regressed during the period of active therapy but recurred at cessation of anti-VEGF treatment.<sup>53,54</sup> This drug's comparative efficacy has limited its use.

### Aflibercept

In the phase 3 VIVID and VISTA studies, 872 eyes with center-involved macular edema were randomized to receive intravitreal injection of aflibercept 2 mg every 4 weeks, 2 mg every 8 weeks after five monthly doses or macular laser.<sup>65</sup> The mean change in best-corrected visual acuity (BCVA) at week 52 from baseline was the primary endpoint. The primary endpoint was superior for aflibercept compared to laser controls at week 52 and sustained through week 100.<sup>66</sup> The results were similar for both dosing groups. The mean change in vision was a gain of 12.5 for 2 mg q4 and 10.7 for 2 mg q8 versus 0.2 letters for laser ( $p < 0.0001$ ) in VISTA, and 10.5 for 2 mg q4 and 10.7 for 2 mg q8 versus 1.2 letters for laser ( $p < 0.0001$ ) in VIVID. Eyes receiving aflibercept had more significant reductions in OCT thickness as compared with controls. Significantly more eyes also gained 15 or more letters from baseline in the aflibercept compared with the laser groups. An analysis of the mean visit-to-visit change in BCVA and central retinal thickness during the upload phase from the 2 mg q4 and the 2 mg q8 datasets showed continual functional and anatomical improvements after the fourth and fifth injections. This study suggests that intensive uploading is beneficial.<sup>67</sup>

### Additional Medical Therapies

Inhibition of protein kinase C, a compound critical in the cascade that activates VEGF expression, was not shown to be of benefit in the treatment or prevention of DME. An oral inhibitor of protein kinase C has been shown to suppress retinal neovascularization in animal models.<sup>68</sup> Recently, a protein kinase C inhibitor has been shown to reduce diabetes-induced hemodynamic abnormalities in patients with diabetic retinopathy and reduce the risk of vision loss in patients with macular edema. It delayed the progression of edema located more than 100  $\mu\text{m}$  from the foveal center to within 100  $\mu\text{m}$  of the foveal center (68% vs. 50%,  $p = 0.003$ ). Initial laser treatment for macular edema was 26% less frequent in eyes of ruboxistaurin-treated patients ( $p = 0.008$ ).<sup>69</sup> However there was no effect of ruboxistaurin on prevention of progression of diabetic retinopathy.<sup>70,71</sup>

In addition to anti-VEGF therapies, there are non-VEGF pathways that may be useful targets in the therapy of DME. One of these is the Tie 2 receptor pathway.<sup>72-74</sup> Inhibition of angiopoietin 2 (Ang2) is being investigated in combination with anti-VEGF therapies. The Boulevard Study is a phase 2 study that is comparing the efficacy of a bispecific antibody (Roche RG7716) to both VEGF and Ang2 with ranibizumab alone. The Ruby Study was a phase 2 study comparing the efficacy of a co-formulation of two drugs (aflibercept and nesvacumab) with aflibercept alone. The Boulevard Study has shown that the bispecific antibody achieved its primary endpoint of efficacy. Mean VA gain at 6 months was significantly improved for the bispecific antibody as compared with ranibizumab alone (3.6 letters difference,  $p = 0.03$ ); mean gain was 13.9 letters from baseline (written communication from Genentech.) The Ruby Study has shown no difference in the primary endpoint between the coformulated drug and aflibercept (written communication from Regeneron).

## Pharmacotherapy for Proliferative Diabetic Retinopathy

The use of anti-VEGF therapy for PDR initially was shown in the pegaptanib sodium for DME studies. In these studies, a few eyes with PDR were inadvertently included, and regression of the PDR occurred.<sup>53,54</sup> This led to specific studies evaluating the use of anti-VEGF for PDR. In a phase 1, prospective, randomized, controlled, open-label study, 20 active PDR patients

were randomly assigned to receive pegaptanib sodium (0.3 mg) every 6 weeks for 30 weeks or PRP laser. In the pegaptanib group, early regression was seen by week 3 (90%) with complete regression by week 12 that was maintained through week 36. In contrast, in the PRP group, 25% showed complete regression, 25% partial, and 50% showed persistent active PDR. Mean change in vision was +5.8 letters in pegaptanib-treated eyes and -6.0 letters in PRP-treated eyes.<sup>53</sup>

The DRCR Protocol S has compared anti-VEGF and PRP for eyes with PDR in a noninferiority study in 394 eyes.<sup>75</sup> Treatment with 0.5 mg ranibizumab (initially every 4 weeks for six injections unless no neovascularization at 4- or 5-month visit) was noninferior to PRP for visual acuity outcomes. Primary outcome was mean change in vision at 2 years compared to baseline. At 2 years, mean visual acuity improved 2.8 letters in the ranibizumab group versus 0.2 letters in the PRP group ( $p < 0.001$  for noninferiority). Both treatments were effective for controlling the PDR and in preventing NVI and visual loss. However, when improvements in visual acuity were evaluated, anti-VEGF was found to result in superior mean visual acuity over the course of 2 years when an area-under-the-curve analysis was performed. Greater numbers of eyes gained vision. Anti-VEGF also had superior visual field outcomes compared to laser. There was also a decreased need for vitrectomies and lower incidence of center-involved macular edema in the anti-VEGF eyes. PRP was rarely given for failure of anti-VEGF to control PDR. There was a lower amount of reduction in visual field.

An analysis of rate of progression of PDR (defined as first occurrence of vitreous hemorrhage, retinal detachment, anterior segment neovascularization, or neovascular glaucoma) showed that eyes treated with ranibizumab had lower rates (34% vs. 42%) of progression than eyes treated with PRP.<sup>76</sup> Incidentally, the risk of progression was higher for eyes receiving pattern scan laser than for eyes receiving conventional PRP (60% vs. 39%).

Despite these results, one needs to weigh other factors that may affect a patient's response to anti-VEGF therapy for PDR. If a patient is not likely to follow up and thus not likely to receive the needed anti-VEGF injections, one should probably not use anti-VEGF and instead proceed with PRP. In patients with PDR and DME, anti-VEGF is a reasonable choice.<sup>75</sup>

More recently, the RIDE and RISE studies have shown eyes treated with monthly ranibizumab were more likely to show improvement and less likely than sham eyes to show progression on the ETDRS retinopathy severity as graded on fundus photographs. These eyes were less likely to develop PDR.<sup>77</sup> Interestingly, patients with PDR had regression to NPDR levels. The DRCR showed that there was no difference in the rate of required pars plana vitrectomy 16 weeks later in eyes with vitreous hemorrhage given intravitreal ranibizumab versus sterile saline.<sup>78</sup>

### Corticosteroids

Even before clinical trials that investigated the long-term benefit of corticosteroids (triamcinolone acetonide) for DME, this treatment was in wide usage. In the short term, good visual results and improved OCT findings are seen in most eyes. However, with repeated injections over time, complications can occur frequently that limit the initial benefit. The DRCR network studies suggest that over 2 years of treatment, monotherapy with triamcinolone acetonide is not superior to laser photocoagulation for DME.<sup>79</sup> At 2 years, mean visual acuity was better in eyes treated exclusively with laser compared to eyes treated exclusively with either 1 mg triamcinolone ( $p = 0.02$ ) or 4 mg triamcinolone ( $p = 0.002$ ) groups.<sup>80</sup> As expected, intraocular pressure rise and cataract onset were greater in the triamcinolone group.

Since monotherapy with one agent is not how most patients are treated in the real world, subsequent studies looked at corticosteroids plus laser. As mentioned earlier, except perhaps in pseudophakic eyes, this combination is not recommended for primary treatment of DME if anti-VEGF agents are available.

There have been corticosteroids other than triamcinolone acetonide, evaluated for treatment of DME. A fluocinolone acetonide intravitreal insert was studied in the Famous Study.<sup>81</sup> The intravitreal inserts provide excellent sustained intraocular release of fluocinolone acetonide for one year or more. In a large trial, the FAME study, 29% of eyes receiving the 0.2  $\mu\text{g}$ /day fluocinolone implant gained three or more lines by year 2, versus 16% in the sham group ( $p = 0.002$ ).<sup>82</sup> Complications included elevation of IOP related events in 37% treated eyes versus 12% controls. Glaucoma surgery was required in 4.8% treated versus 0.5% controls. Cataract as an adverse event occurred in 82% of treated eyes, and 80% of treated eyes underwent cataract extraction over a period of 36 months versus corresponding data of 50% and 27% in the control group. Eyes with chronic DME had higher proportions of gain of 15 or more letters from baseline compared with

controls.<sup>83</sup> The study concluded that the fluocinolone implant is effective in eyes with chronic macular edema. The U.S. Food and Drug Administration (FDA) approval notes that this therapy is not to be used unless the eye has been previously treated with corticosteroids and has not had an elevation in IOP.

The dexamethasone intravitreal implant containing 700 µg dexamethasone (Ozurdex, Allergan, Irvine, CA) in a solid polymer drug delivery system that is also approved by the FDA for treatment of diabetic macular edema, in addition to macular edema from vein occlusions and uveitis. The MEAD study showed that 0.7 mg dexamethasone resulted in 22% treated eyes versus 12% sham eyes gaining 15 or more letters.<sup>84,85</sup> Also, dexamethasone-treated eyes had more significant reductions in CST on OCT (−112 µg versus −42 µg,  $p < 0.001$ ).

The BEVORDEX Study compared dexamethasone treated eyes and bevacizumab in a phase 2 study.<sup>86</sup> No significant differences were seen between the drugs for visual acuity or CST change by OCT at 24 months. However, 74% of dexamethasone-treated eyes versus 48% of bevacizumab-treated eyes had a rise in IOP of 5 mm Hg or more.

In vitrectomized eyes, the Champlain study showed that 55 vitrectomized eyes with treatment-resistant DME had statistically and clinically significant improvements in both visual acuity and vascular leakage with treatment. In fact, 30% gained 10 more letters.<sup>87</sup>

## Surgical Therapy

### Panretinal Photocoagulation

The Diabetic Retinopathy Study proved that both xenon arc and argon laser PRP significantly decrease the likelihood of progression of eyes with high-risk characteristics (HRC) to severe visual loss.<sup>88</sup> Eyes with HRC are defined as those with NVD greater than one fourth to one third of a disc area, those with any NVD and vitreous hemorrhage, or those with NVE greater than one-half the disc area and vitreous or preretinal hemorrhage.

The exact mechanism by which PRP works remains unknown. One hypothesis is that PRP decreases the production of vasoproliferative factors by eliminating areas of hypoxic retina. An alternative hypothesis suggests that by thinning the retina, PRP increases oxygenation of the remaining retina by allowing increased diffusion of oxygen from the choroid. Yet another hypothesis is that PRP leads to an increase in vaso-inhibitors by directly stimulating the retinal pigment epithelium to produce inhibitors of vasoproliferation.<sup>89</sup>

The goal of PRP is to arrest or to cause regression of the neovascularization. The recommended therapy is 1200–2000 burns that are 500 µm in diameter delivered through the Goldmann lens, or the equivalent number when using 200 µm burns delivered through the Rodenstock panfunduscope lens or Volk SuperQuad lens. The burns should be intense enough to lightly whiten the overlying retina using a duration of 0.1 second (see Fig. 6.22.5). There are newer lasers that deliver shorter bursts of laser energy that result in control of the neovascularization.

Some retinal specialists feel that there is no upper limit to the total number of burns and that treatment should be continued until regression occurs.<sup>90</sup> The only prospective, controlled study found that eyes that received supplementary PRP treatment had no improved outcome over those that received standard PRP only.<sup>91</sup> About two thirds of eyes with HRC that receive PRP have regression of their HRC by 3 months after treatment.

The ETDRS found that PRP significantly retards the development of HRC in eyes with very severe NPDR and macular edema.<sup>29</sup> After 7 years of follow-up, 25% of eyes that received PRP developed HRC as compared with 75% of eyes in which PRP was deferred until HRC developed. Nevertheless, the ETDRS concluded that treatment of severe NPDR and PDR short of HRC was not generally indicated for three reasons.

First, after 7 years of follow-up, 25% of the eyes assigned to deferral of PRP had not developed HRC. Second, when patients are closely monitored and PRP is given as soon as HRC develops, severe visual loss can be prevented. After 7 years of follow-up, 4.0% of eyes that did not receive PRP until HRC developed had a visual acuity of 5/200 or less, compared with 2.5% of eyes assigned to immediate PRP. The difference was neither clinically nor statistically significant. Third, PRP has significant complications. It often causes decreased visual acuity by increasing macular edema or by causing macular pucker.<sup>92,93</sup> Fortunately, the edema frequently regresses spontaneously over 6 months, but the visual field usually is moderately, but permanently, decreased. Color vision and dark adaptation, which often are already impaired, also are worsened by PRP.<sup>94</sup> However, if both eyes have severe NPDR, the ETDRS reported that PRP was not unreasonable, especially in patients who are unlikely to follow up closely.

Recently the pattern lasers have enabled semi-automated laser photocoagulation.<sup>95</sup> These lasers allow various patterns of laser spots to be given within a fraction of the time usually required when using traditional lasers. The duration of the laser application (usually 10–30 milliseconds) is also shorter than traditional lasers (100–300 milliseconds). Studies have shown that more laser spots are needed with increasing severity of PDR.<sup>96</sup> In a prospective study in which one eye was assigned to pattern laser single session and the other eye to multisection conventional PRP laser, control of PDR was achieved with less associated pain or complications.<sup>97</sup> However, applying the same number of spots used with traditional lasers does not achieve sustained regression of the lesions, probably because more laser spots are required to treat the same area of retina achieved with traditional lasers.<sup>98</sup>

### Peripheral Retinal Cryotherapy

Peripheral retinal cryotherapy is used to treat HRC in eyes with media too hazy for PRP. Reported benefits include resorption of vitreous hemorrhages and regression of NVD, NVE, and NVI. The main complication is the development or acceleration of traction retinal detachment in 25%–38% of eyes.<sup>99</sup> Therefore, this treatment should be avoided in patients with known traction retinal detachment, and all patients must be monitored carefully. In the current era of anti-VEGF therapy this option is mostly historical. This option is probably best reserved for those eyes with no visual potential and recalcitrant PDR that has been unresponsive to PRP or in which PRP cannot be applied. The DRCR Protocol AB will investigate the utility of anti-VEGF in eyes with vitreous hemorrhage compared to pars plana vitrectomy.

### Focal Laser for Macular Edema

Patz<sup>100</sup> was the first to show that argon laser photocoagulation decreases or stabilizes macular edema. Later, the ETDRS confirmed his results. The ETDRS<sup>29</sup> defined clinically significant macular edema as:

- Retinal thickening involving the center of the macula, or
- Hard exudates within 500 µm of the center of the macula (if associated with retinal thickening), and
- An area of macular edema greater than one disc area but within 1 disc diameter of the center of the macula.

In the era of spectral-domain optical coherence tomography (SD-OCT) imaging, intraretinal cysts are seen on SD-OCT imaging in eyes with relatively good visual acuity and no clinical thickening. There is no clinical trial to date that has addressed management of these “subclinical DME” eyes.

The ETDRS focal laser treatment strategy was to photocoagulate all leaking microaneurysms further than 500 µm from the center of the macula and to place a grid of 100–200 µm burns in areas of diffuse capillary leakage and in areas of capillary nonperfusion (Fig. 6.22.8). After 3 years of follow-up, 15% of eyes with clinically significant macular edema had doubling of the visual angle as opposed to 32% of untreated control eyes.<sup>101</sup> The ETDRS also showed that PRP should not be given to eyes with clinically significant macular edema unless HRC are present.<sup>29</sup> Patients with macular edema who have the best prognosis for improved vision have circinate retinopathy of recent duration or focal, well-defined leaking areas and good capillary perfusion surrounding the avascular zone of the retina. Patients with an especially poor prognosis have dense lipid exudate in the center of the foveola (Fig. 6.22.9). Other poor prognostic signs include diffuse edema with multiple leaking areas, extensive central capillary nonperfusion, increased blood pressure, and CME.<sup>101</sup> Nevertheless, the ETDRS found that even eyes with these adverse findings still benefited from treatment when compared with control eyes. Side effects of the focal laser include some loss of central vision, central scotomas, and decreased color vision. In addition, the retinal pigment epithelium (RPE) and retinal atrophy associated with the laser scars can enlarge over time and may encroach on fixation.<sup>102</sup> Following publication of the ETDRS, clinicians now use laser burns that are lighter and less intense to limit progressive laser scar expansion and the attendant visual side effects. Because of these side effects, investigators turned to pharmacological agents to treat DME. One of the first agents used was intravitreal triamcinolone acetate. However, as discussed earlier, the effect is transient and there is a high risk of cataract progression and secondary glaucoma.<sup>103</sup> Eyes with macular ischemia and better baseline vision may have less vision improvement with intraocular corticosteroids.<sup>103–104</sup> Anti-VEGF agents are more commonly employed due to their higher rates of efficacy and lower rates of complications.

Pattern laser results in barely visible 10 millisecond laser spots that reduce retinal edema with minimization of scar formation.<sup>95</sup> It will be

**Fig. 6.22.8 Macular Edema.** (A) In an eye previously treated with panretinal photocoagulation. (B) Midphase of fluorescein angiography showing microaneurysms, large areas of capillary nonperfusion, and slight enlargement of the foveal avascular zone. (C) Late phase of fluorescein angiography showing diffuse capillary leakage. (D) Grid pattern of focal macular photocoagulation in same eye.

**Fig. 6.22.9 Hard Exudate Plaque in the Center of the Macula.**

interesting to see whether combinations of pharmacotherapy and lighter application strategies can achieve durability with similar rates of visual efficacy as seen with anti-VEGF monotherapy and deferred argon laser. Micropulse lasers are also being studied for treatment of DME. High-density, subvisible, diode, micropulse lasers can achieve reduction of DME without laser-induced retinal damage.<sup>105–107</sup> A prospective, randomized, controlled, double-masked clinical trial has compared outcomes achieved with modified ETDRS focal/grid photocoagulation (42 patients), normal density subthreshold micropulse (39 patients), or high-density subthreshold micropulse (42 patients) in previously untreated DME eyes with baseline best corrected visual acuity worse than 20/40 and better than 20/400. All groups showed a significant progressive reduction of central macular thickness throughout the study ( $p < 0.001$ ). However, the visual acuity results were

best for the high-density subthreshold micropulse group (0.25 logMAR) and then the modified ETDRS group (0.08 logMAR). No improvement was found in the normal-density subthreshold micropulse group (0.03 logMAR). More research is needed in this area to further evaluate this new laser technique and to compare outcomes with anti-VEGF monotherapy of combination therapies.<sup>108</sup>

In summary, the Diabetic Retinopathy Study and the ETDRS conclusively proved that timely laser photocoagulation of diabetic retinopathy can reduce severe visual loss by 95%.<sup>109</sup> Such treatment makes sense not only from the humanitarian point of view, but also from a cost-effectiveness viewpoint. It has been estimated that ETDRS-style therapy saves \$250–500 million per year in the United States by enabling patients to avoid disability and welfare.<sup>110</sup> More recently, anti-VEGF therapies have raised our ability to improve visual acuity and hopefully will result in further avoidance of disability for our patients. Laser remains the treatment of choice for clinically significant DME that is *not* foveal involving.

### Vitrectomy in Diabetic Retinopathy

Vitrectomy plays a vital role in the management of severe complications of diabetic retinopathy. The major indications are nonclearing vitreous hemorrhage, macular-involving or macular-threatening traction retinal detachment, and combined traction-rhegmatogenous retinal detachment. Less common indications are macular edema with a thickened and taut posterior hyaloid, epiretinal membrane, severe preretinal macular hemorrhage, and neovascular glaucoma with cloudy media.<sup>111</sup>

To evaluate whether early vitrectomy (in the absence of vitreous hemorrhage) might improve the visual prognosis by eliminating the possibility of later traction macular detachment, the Diabetic Retinopathy Vitrectomy Study (DRVS) randomized 370 eyes with florid neovascularization and visual acuity of 20/400 or better to either early vitrectomy or to observation.<sup>112</sup> After 4 years of follow-up, approximately 50% of both groups had 20/60 or better, and approximately 20% of each group had light perception or worse. Thus the results indicate that such patients probably do not benefit from early vitrectomy. They should be observed closely so that vitrectomy, when indicated, can be undertaken promptly.

If a patient has a vitreous hemorrhage severe enough to cause a visual acuity of 5/200 or less, the chances of visual recovery within 1 year are only about 17%.<sup>113</sup> The DRVS randomized patients who had a visual acuity of 5/200 or less for more than 6 months into two groups: those who received an immediate vitrectomy and those whose vitrectomy was deferred for a further 6 months.<sup>113</sup> The goals of surgery were to release all anterior-posterior vitreous traction and to perform a complete PRP to reduce the incidence of recurrent hemorrhage. Of those who had deferred vitrectomy, 15% had a final visual acuity of 20/40 or better as opposed to 25% of those who had an immediate vitrectomy. In patients with type 1 diabetes, 12% of those who had a deferred vitrectomy had a final visual acuity of 20/40 or better, as opposed to 36% of those who had an immediate vitrectomy. The reason for this discrepancy is thought to be excessive growth of fibrovascular proliferation during the waiting period. For this reason, the DRVS concluded that strong consideration should be given to immediate vitrectomy, especially in type 1 diabetics (in type 2 diabetics, the final visual results were similar). Currently, with improved surgical techniques and tools, clinicians no longer defer surgery for diabetic vitrectomy. Patients with bilateral visual loss because of vitreous hemorrhage, rubeosis and hemorrhage, recurring hemorrhage, and known traction retinal detachment close to the macula should be offered early vitrectomy. If surgery is deferred, ultrasonography should be performed at regular intervals to make sure that traction retinal detachment is not developing behind the hemorrhage. In patients who have recurrent vitreous hemorrhage after vitrectomy, a simple outpatient air-liquid exchange may restore vision without the need for a repeat vitrectomy.<sup>114</sup>

Traction retinal detachments are usually a much greater challenge. In general, unless the macula becomes involved, observation is the best therapy for these patients, because in most cases the detachment does not progress into the macula. These patients should be counseled to seek immediate attention should macular vision suddenly be lost. The surgical objectives are to clear the media, to release all anterior-posterior traction, to release tangential traction via delamination or segmentation (cutting the fibrotic bridges between areas of tractional detachment), and to perform endophotocoagulation. The prognosis is best in patients who have small areas of traction. The prognosis is poorest in eyes with tabletop detachments, significant preoperative vitreous hemorrhage, no prior PRP, and advanced fibrovascular proliferation. If a lensectomy is required or if iatrogenic breaks are created, the results are poorer.<sup>115</sup> Approximately 60%–70% of patients have improved visual acuity and a final visual acuity of 20/800 or better, but 20%–35% have decreased vision after vitrectomy. Cases with severe peripheral fibrovascular proliferation also may require a scleral buckling procedure.<sup>116</sup> Repeated operations are required in about 10% of patients, most commonly for rhegmatogenous retinal detachment and recurrent vitreous hemorrhage.<sup>117</sup>

A possible cause of failure following an otherwise successful vitrectomy is NVI resulting in neovascular glaucoma. The risk is higher if there is preoperative NVI (33% versus 17%), if there is persistent retinal detachment after surgery, if the lens is removed during surgery, and if there is florid NVD. In eyes without these factors, the incidence of neovascular glaucoma is only about 2%. The pathogenesis of this complication is unknown. Some investigators believe that removal of the vitreous allows vasoproliferative factors produced in hypoxic retina to diffuse forward to the iris. Others believe that following vitrectomy increased oxygen diffusion occurs posteriorly out of the anterior chamber, thereby lowering its oxygen tension too far. Fortunately, if an eye does not develop iris neovascularization during the first 4–6 months after vitrectomy, it rarely does so later.<sup>118</sup> With the advent of anti-VEGF therapy, there is more hope for these eyes.

Another vision-threatening complication is neovascularization that originates from the anterior retina and extends along the anterior hyaloid to the posterior lens surface (anterior hyaloidal fibrovascular proliferation).<sup>119</sup> This is more common in young, phakic diabetics who have extensive capillary nonperfusion.

Vitrectomy for diffuse macular edema is controversial. Evidence indicates that patients with an abnormally taut posterior hyaloid are more likely to have visual improvement and reduction of edema as compared to patients with a posterior vitreous separation. Removal of the internal limiting membrane over the macula may be beneficial.<sup>120,121</sup>

## CONCLUSIONS
